- The generic designation of ceruminoma should be avoided; ceruminal gland neoplasms should be specifically diagnosed according to tumor type.
- The classification of ceruminal gland neoplasms includes benign and malignant tumors ([Box 24-2](#)):
 - Benign ceruminal gland tumors include:
 - Ceruminal gland adenoma
 - Pleomorphic adenoma
 - Syringocystadenoma papilliferum
 - Malignant ceruminal gland tumors include:
 - Ceruminal gland adenocarcinoma
 - Adenoid cystic carcinoma
 - Mucoepidermoid carcinoma

Ceruminal Gland Adenoma

(Figs. 24-2 through 24-4)

Synonym: Ceruminoma**Clinical**

- Affect men more often than women; over a wide age range but is most frequently seen in the fifth to sixth decades of life
- Symptoms include a slow-growing external auditory canal mass or blockage, hearing difficulty, and infrequently, otic discharge.

Pathology**Gross**

- Skin-covered, circumscribed, polypoid, or rounded mass ranging in size from 1 to 4 cm in diameter
- Ulceration is uncommon and may suggest a malignant neoplasm.

Histology

- Unencapsulated but well-demarcated glandular proliferation
- Glands vary in size and may have various combinations of growth patterns including solid, cystic, and

**Fig. 24-2. Ceruminal gland adenoma.**

Ceruminal gland adenoma resection specimen appearing as a skin-covered lesion with a glistening, golden yellow appearance.

**Fig. 24-3. Ceruminal gland adenoma.**

At low magnification ceruminal gland adenoma is circumscribed but unencapsulated in its depth (*right*).

papillary; a back-to-back glandular pattern is commonly seen.

- Glands are composed of two cell layers:
 - Inner or luminal epithelial cell is cuboidal or columnar appearing with an eosinophilic cytoplasm and a decapitation-type secretion (apical “snouts”) characteristic for apocrine-derived cells.
 - Outer cellular layer is a spindle cell with a hyperchromatic nucleus and represents myoepithelial or basal cells.
- Intracytoplasmic golden yellow-brown granular-appearing pigment can be seen in the inner lining (luminal) cells representing cerumen.
- Cellular pleomorphism and mitoses can be seen but are not prominent.

Fig. 24-4. Ceruminal gland adenoma.

A, The glands in ceruminal gland adenoma are composed of two cell layers, including inner or luminal epithelial cells with a cuboidal to columnar appearance and an eosinophilic cytoplasm with a decapitation-type secretion (apical "snouts") characteristic for apocrine-derived cells and the outer cellular (myoepithelial or basal cell) layer composed of cells with hyperchromatic nuclei. **B**, Intracytoplasmic golden yellow-brown granular-appearing pigment can be focally seen in the inner lining cells indicative of cerumen production. Immunohistochemical staining (not shown) includes strong and diffuse CK7 staining in luminal cells and CK5/6, S100 protein, and p63 in the basal cells.

- Intervening stroma shows a variable admixture of fibromyxomatous tissue.
- Histochemistry:
 - Diastase-resistant, PAS-positive, and/or mucicarmine-positive intracytoplasmic and/or intraluminal material may be seen.
- Immunohistochemistry:
 - Luminal cells:
 - Strongly and diffusely immunoreactive with CK7; CD117 positive
 - Myoepithelial or basal cells:
 - CK5/6, S100 protein, and p63 positive

- Ultrastructure:
 - Epithelial (apocrine cell) and myoepithelial cell differentiation including:
 - Epithelial cells show features of apocrine cells, including apocrine caps, microvilli, cell junctions, secretory granules, vacuoles, lipid droplets, and siderosomes.
 - Concentric membranous bodies of the endoplasmic reticulum, phagocytic activity of the tumor cells, intracytoplasmic lumina, ciliated cells, and also spiny collagen in the tumor stroma can be seen.

Differential Diagnosis

- Pleomorphic adenoma of ceruminal or parotid gland origin
- Middle ear adenoma:
 - May perforate the tympanic membrane and appear to present as an external auditory canal mass, creating potential difficulty in differentiation from a ceruminal gland adenoma
 - Histologic features of both tumor types should allow for relatively easy differentiation from one another.
- Ceruminal gland adenocarcinoma

Treatment and Prognosis

- Complete surgical excision is the preferred treatment and is curative.
- Recurrence of the tumor can occur and relates to inadequate surgical excision.

OTHER CERUMINAL GLAND BENIGN NEOPLASMS

Pleomorphic Adenoma of Ceruminal Gland Origin (Fig. 24-5)

- Uncommon tumor
- Histology is similar to pleomorphic adenomas of salivary gland origin, including a variable admixture of epithelial and myoepithelial components set in a myxoid to chondromyxoid stroma.

Syringocystadenoma Papilliferum of Ceruminal Gland Origin

(Figs. 24-6 and 24-7)

- Benign tumor of apocrine gland origin that usually occurs on the scalp and face area
- May originate in the external auditory canal from ceruminal glands
- Histology is similar to tumors of the more common cutaneous sites and to the salivary gland tumor termed sialadenoma papilliferum (see Section 6).

Fig. 24-5. Ceruminous gland pleomorphic adenoma.

Pleomorphic adenoma of ceruminous gland origin presenting as an external auditory canal mass and characterized by the presence of a subepithelial proliferation of glandular/tubular structures with myoepithelial cells in a chondromyxoid stroma.

Fig. 24-6. Syringocystadenoma papilliferum.

Syringocystadenoma papilliferum appearing as a small discrete skin-covered nodule on the concha.

A

B

Fig. 24-7. Syringocystadenoma papilliferum.

A, The histology of syringocystadenoma papilliferum includes the presence of a cup-shaped cystic lesion filled by papillary proliferation and communicating with the skin surface. **B**, The papillary fronds are covered by a dual cell layer, including luminal columnar cells with eosinophilic cytoplasm showing apical snouting and inner layer of flattened cuboidal cells; the core of the papillary fronds is composed of lymphoplasmacytic inflammatory cell infiltrate.

BENIGN MESENCHYMAL TUMORS OF THE EXTERNAL EAR

Epithelioid Hemangioma (EH)

(Figs. 24-8 to 24-9)

- Epithelioid hemangioma (EH), also known as angiolymphoid hyperplasia with eosinophilia (ALHE), has been a controversial lesion with regard to its classification (reactive proliferation or neoplastic process) and its relationship to Kimura disease:
 - A reactive cause especially secondary to trauma has been proposed but a neoplastic origin is favored.
 - Considered to represent the benign end of the spectrum of vascular tumors characterized by

epithelioid endothelial cells, many of which are rich in lymphocytes and eosinophils

- Malignant end of the spectrum includes epithelioid hemangioendothelioma and epithelioid angiosarcoma.
- Shares features with Kimura disease, but the clinical and histologic differences allow these entities to be separated and considered as distinct clinicopathologic entities (Table 24-1)

Clinical

- No gender predilection; most frequently occurs in the third through fifth decades of life
- Subcutaneous proliferation with a predilection for the external ear (auricle and external canal), as well as other head and neck sites, including the scalp and forehead (Fig. 24-8)
- Symptoms include pruritus and bleeding following scratching; regional lymphadenopathy and peripheral eosinophilia are uncommon but may be present.

- History of trauma elicited in a number of cases, as well as the microscopic impression of vascular damage, and the demonstration of immunoglobulin deposits in the vessels have led several observers to favor a reactive or reparative etiology.
- Hormonal influences may play a role in some cases, as suggested by the association with pregnancy in some patients and by the age and gender distribution of the disease.
- Human herpesvirus 8 (HHV-8) has not been identified in association with EH.

Pathologic Features

Gross

- Characterized by single or multiple, pink to red-brown indurated cutaneous papules or subcutaneous nodules
- Measure from a few millimeters to 1 cm in diameter
- Clusters of papules may coalesce to form large plaque-like lesions.

TABLE 24-1 Epithelioid Hemangioma (EH) versus Kimura Disease

	EH	Kimura Disease
Gender	M = F or F > M	M > F
Peak incidence	3rd to 5th decades	2nd to 3rd decades
Head and neck site	Periauricular, forehead	Postauricular, scalp
Lymphadenopathy	Absent to rare	Common
Peripheral eosinophilia	<25%	>50%
Location	More superficial situated in subcutaneous, dermis	More deeply situated extending to the subcutaneous fat, fascia, and skeletal muscle
Histology	Nodular vascular proliferation lined by plump-appearing (epithelioid) endothelial cells with pleomorphic changes and hyperchromatic nuclei, and accompanied by a prominent inflammatory cell infiltrate with variable admixture of lymphocytes, histiocytes, plasma cells, and eosinophils	Vascular component is sparse with minimal epithelioid endothelial changes; lymphoid proliferation predominates, but prominent eosinophilic cell infiltrate, including eosinophilic microabscesses can be seen; associated fibrosis is present

Fig. 24-8. Epithelioid hemangioma.

Epithelioid hemangioma appearing as multiple superficial dull red-appearing papules; some of the papules appear to coalesce into plaque-like lesion.

Fig. 24-9. Epithelioid hemangioma.

A, Epithelioid hemangioma of the ear characterized by the presence of subcutaneous nodular (lobular) growth composed of a proliferation of vascular spaces, varying in size from the dimensions of a capillary to medium-sized arteries and veins, and a mixed chronic inflammatory cell infiltrate. **B**, The vascular spaces are lined by plump-appearing (epithelioid) endothelial cells and surrounding inflammatory cells composed of mature lymphocytes, eosinophils, and histiocytes.

Histology (Fig. 24-9)

- Characterized by a nodular vascular proliferation accompanied by a variably dense lymphoid infiltrate rich in eosinophils
- Process is circumscribed but not encapsulated and may involve the subcutis or dermis, or both.
- Vascular component:
 - Varies in size from capillary to medium-sized arteries and veins
 - Vascular spaces are lined by plump-appearing (epithelioid) endothelial cells with pleomorphism, hyperchromatic nuclei, copious eosinophilic cytoplasm, and inconspicuous nucleoli.
 - Frequently, the endothelial cells protrude into the vessel lumen in a “hobnail” fashion, creating a cobblestone-like appearance.
 - Increased mitotic activity and moderate to marked nuclear pleomorphism not identified
- Lobular arrangement of the proliferating vessels may be evident; however, the distribution of vessels is more haphazard in some lesions:
 - Vessels vary from irregular, poorly canalized thin-walled spaces to rounded well-formed vessels with thickened walls.
 - In some cases there is evidence of disruption or damage to some of the involved vessels.
 - Origin from a small artery or vein is common but may depend on adequate sampling.
 - Common for the entire lesion to be intravascular (intravascular EH):
 - Differ from “conventional” EH by virtue of predominant spindle cell (pericytic) component
 - Predominantly occurs in young to middle-aged adults
 - Solitary nodule most often in head and neck or upper limb

- Inflammatory component surrounds the vascular proliferation and is characterized by an admixture of lymphocytes, histiocytes, and eosinophils; on occasion, eosinophils may be few in number or absent.
- Immunohistochemistry:
 - Endothelial cells are:
 - CD31, ERG, and to a lesser extent CD34 positive
 - Glucose transporter protein 1 (GLUT1) negative
 - Rarely cytokeratin positive

Differential Diagnosis

- Lobular capillary hemangioma:
 - Prominence of epithelioid endothelial features and associated lymphoplasmacytic and eosinophilic infiltrate contrast with findings in hemangiomas.
- Infantile hemangioma:
 - GLUT1 positive
- Angiosarcoma:
 - Shows a diffusely infiltrative lesion composed of anastomosing vascular channels lined by pleomorphic cells with increased mitotic activity
 - Presence of the characteristic inflammatory infiltrate in EH typically not found in angiosarcoma

Treatment and Prognosis

- Local surgical excision or desiccation are the preferred treatments and are curative:
 - Rarely, lesions may regress.
- Recurrence reported in up to one-third of cases
- Metastasis virtually never occurs.
- Superficial radiotherapy results in at least partial response in the majority of patients.
- Intralesional or systemic steroids, cryotherapy, and intralesional vincristine, bleomycin, and fluorouracil not proven to be curative

Kimura Disease (Fig. 24-10)

Clinical

- Not considered synonymous with EH
- Occurs in subcutis of the head and neck; other less common sites of involvement include groin, extremities, and chest wall
- In contrast to EH:
 - Occurs primarily in Asians and tends to affect males
 - Often associated with regional lymphadenopathy and peripheral eosinophilia
 - Increased serum immunoglobulin E (IgE), proteinuria, and nephrotic syndrome may occur as part of the disease.

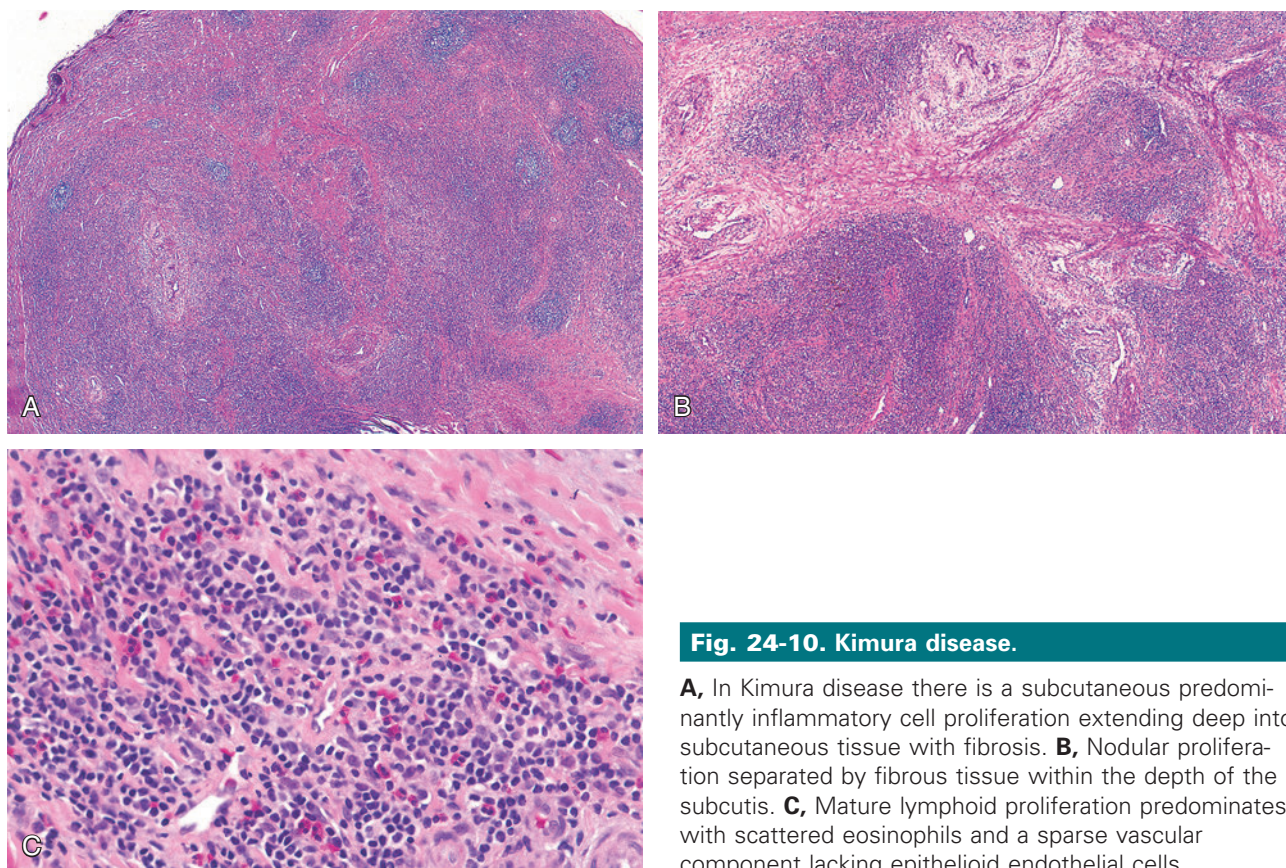

Fig. 24-10. Kimura disease.

A, In Kimura disease there is a subcutaneous predominantly inflammatory cell proliferation extending deep into subcutaneous tissue with fibrosis. **B**, Nodular proliferation separated by fibrous tissue within the depth of the subcutis. **C**, Mature lymphoid proliferation predominates with scattered eosinophils and a sparse vascular component lacking epithelioid endothelial cells.

- Tend to be larger lesions that are predominantly subcutaneous nodules with a tendency to occur in locations other than in the head and neck
- Etiology is unknown:
 - Presence of peripheral eosinophilic and elevated serum IgE suggests immunologic reaction to an unknown stimulus.

Pathology

Histology

- Shares histologic features with EH but differences are seen, including:
 - Lymphoid proliferation, including germinal centers, predominates; the vascular component is sparse and exhibits minimal epithelioid endothelial changes.
 - Lesion is usually located much deeper than EH, often extending to the fascia and to skeletal muscle, and the subcutaneous fat is usually fibrotic.
 - Eosinophils are always numerous in Kimura disease but may be sparse or even absent in EH.
 - Eosinophilic epithelioid granulomatous reaction and/or eosinophilic microabscess formation may be identified.

Differential Diagnosis

- Lobular capillary hemangioma
- Angiosarcoma

Treatment and Prognosis

- Local surgical excision or desiccation are the preferred treatments and are curative.
- Recurrence occasionally occurs.
- Malignant transformation or association with malignancy not reported

OTHER BENIGN MESENCHYMAL NEOPLASMS OF THE EXTERNAL EAR AND AUDITORY CANAL

- Mesenchymal tumors of the external auditory canal are rare and include osteoma, chondroma, leiomyoma, schwannoma, and myxomas.

Osteoma

- In contrast to exostosis, osteomas are true neoplasms of bone capable of unlimited growth.
- Occurs in the external auditory canal presenting as an asymptomatic solitary mass
- Histologically is composed of mature bone with associated intraosseous fibrovascular tissue

Treatment and Prognosis

- Surgery is curative.

Myxomas of the External Ear and External Auditory Canal (Fig. 24-11)

- Described in Carney complex as an autosomal-dominant syndrome complex that includes:
 - Cardiac myxomas:
 - May be associated with peripheral tumor emboli
 - Approximately one-quarter of all patients with cardiac myxomas die of its complications.
 - Cutaneous myxomas:
 - Tend to appear in early adulthood
 - Predilection for eyelids
 - Range from small sessile papules to large pedunculated, finger-like lesions
 - In most cases are multiple
 - Found in dermis or subcutis
 - Usually circumscribed
 - Significant percentage of patients may have myxoma of external ear:
 - 85% of patients with myxoma of external ear have Carney complex
 - Spotty pigmentation:
 - Lentigines on face and vermilion border of lips
 - Blue nevi including epithelioid blue nevi
 - Endocrine disease/tumors:
 - Primary pigmented nodular adrenocortical disease causing Cushing syndrome
 - Pituitary adenoma causing acromegaly

Fig. 24-11. External auditory canal myxoma.

Myxoma of the external auditory canal chiefly consisting of a myxoid/mucoid matrix and the presence of a relatively hypocellular proliferation of spindled to stellate cells with tiny, uniform nuclei. Slit-like capillary vessels are present but there is an absence of a delicate plexiform capillary vascular network.

- Sexual precocity associated with testicular lesions (e.g., Sertoli cell tumor)
- Thyroid diseases (hyperplasia)
- Increase risk of pancreatic ductal and acinar cell neoplasms
- Psammomatous melanotic schwannoma
- Occasionally associated with breast lesions including multifocal myxoid fibroadenomas and myomatosis
- Most patients with Carney complex harbor mutation of *PRKARIA* gene located at 17q22-24 encoding regulatory R1 alpha subunit of protein kinase A.
- Histology characterized by the presence of sparse cytologically bland spindle- and stellate-shaped cells in abundant myxoid stroma and prominent capillary vasculature:
 - Lesion consists chiefly of muroid material in which are suspended a loose framework of reticulin fibers.
 - Cellular component consists of a population of spindled to stellate cells with tiny pyknotic nuclei and delicate cytoplasmic process.
 - Cellular pleomorphism is not seen.
 - Periphery of the tumor is surrounded by a pseudocapsule of condensed reticulin fibers and compressed host tissue, particularly skeletal muscle.
 - Often associated with basaloid proliferation of overlying epithelium:
 - May result in misdiagnosis of basal cell carcinoma or trichofolliculoma
 - Myxoid matrix in myxoma stains with alcian blue and is hyaluronidase sensitive
 - Mucicarmine and colloidal iron stain the myxoid material.
 - Immunohistochemistry of cellular component includes:
 - CD34 and vimentin positive

- Cells may stain for actins and/or desmin, suggesting myofibroblastic differentiation.
- Typically negative for S100 protein, MUC4, cytokeratins

Differential Diagnosis

- Myxoid neoplasms:
 - Myxoid change occurs in a variety of benign neoplasms, including neurofibroma, neurilemmoma, and lipoma, may mimic myxoma, especially in limited biopsy material.
 - Of greater concern is that the histologic pattern in myxomas may mimic myxoid soft tissue malignancies, which are much more common in this location, particularly embryonal rhabdomyosarcoma, and less commonly undifferentiated pleomorphic sarcoma, low-grade fibromyxoid sarcoma, myxoid liposarcoma, and myxoid chondrosarcoma.
 - In contrast to myxoma, sarcomas display:
 - Much greater cellularity
 - A richer vascular pattern often with delicate plexiform capillary vascular network
 - Differing cytologic features including cellular pleomorphism with increased mitotic figures; multinucleated giant cells in undifferentiated pleomorphic sarcoma; cytoplasmic MUC4 in low-grade fibromyxoid sarcoma; lipoblasts in liposarcoma; rhabdomyoblasts in rhabdomyosarcoma; and atypical chondroblasts in chondrosarcoma are distinctive features for these sarcoma types.

Treatment and Prognosis

- Surgery is the preferred treatment.
- Although soft tissue myxomas lack a discrete capsule, they rarely recur after excision.

BENIGN NEOPLASMS OF THE MIDDLE EAR AND TEMPORAL BONE

MIDDLE EAR ADENOMA (MEA)

(Figs. 24-12 through 24-14)

Definition: Benign glandular neoplasm arising from the middle ear mucosa.

Clinical

- Generally considered an uncommon neoplasm
- No gender predilection; occurs over a wide age range but is most common in the third to fifth decades of life

- Any portion of the middle ear may be affected, including the eustachian tube, mastoid air spaces, ossicles, and chorda tympani nerve.
- Most common symptom is that of unilateral conductive hearing loss:
 - Fullness, tinnitus, and dizziness may also occur.
 - Pain, otic discharge, and facial nerve paralysis rarely occur and may be indicative of a malignant process.
- Otoscopic examination in the majority of cases will identify an intact tympanic membrane with tumor

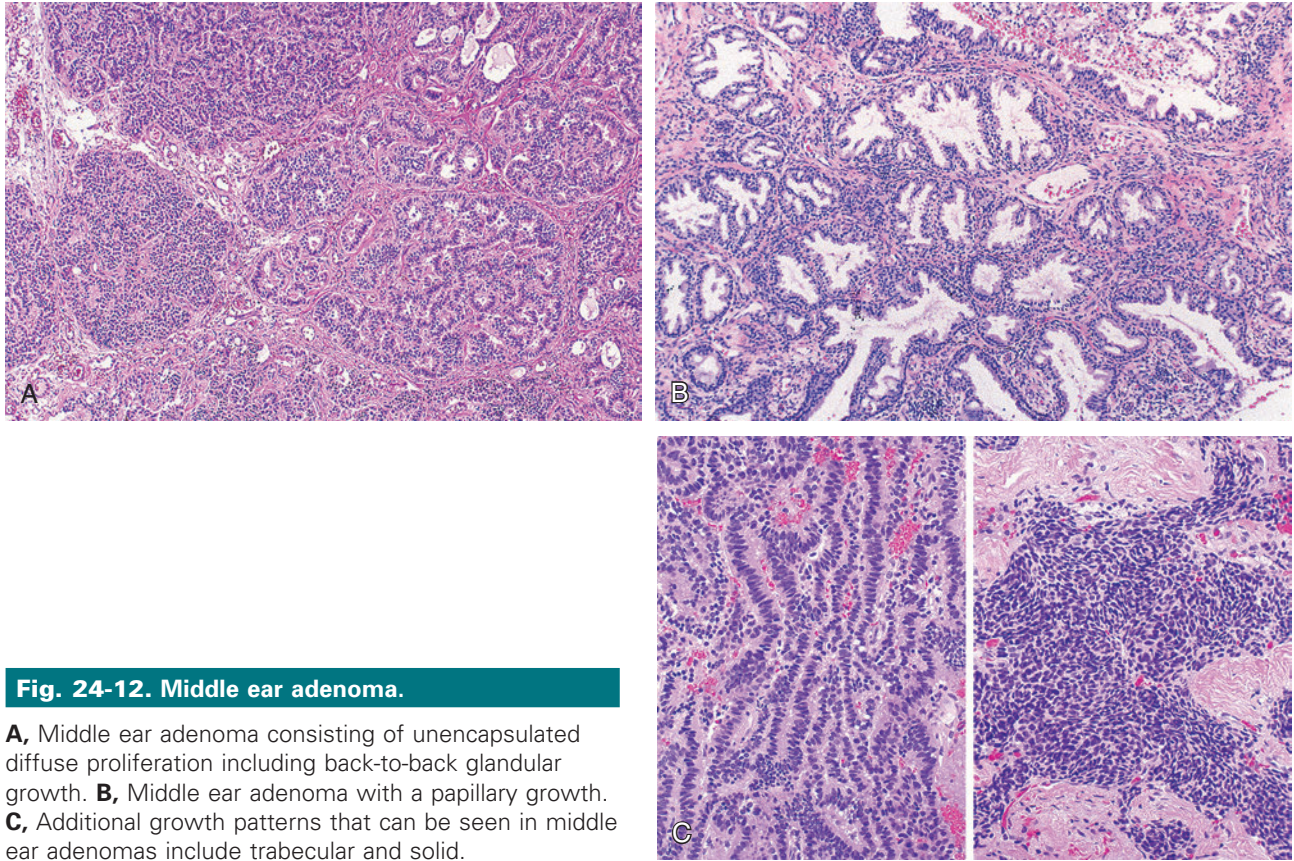

Fig. 24-12. Middle ear adenoma.

A, Middle ear adenoma consisting of unencapsulated diffuse proliferation including back-to-back glandular growth. **B,** Middle ear adenoma with a papillary growth. **C,** Additional growth patterns that can be seen in middle ear adenomas include trabecular and solid.

Fig. 24-13. Middle ear adenoma.

A, Middle ear adenoma showing complex growth composed of a single layer of cuboidal to columnar cells with a varying amount of eosinophilic cytoplasm and round to oval nuclei. **B,** Middle ear adenomas often have a cellular component predominated by plasmacytoid cells, as seen in glandular and solid foci. **C,** Diffuse (solid) cellular proliferation composed of dyscohesive plasmacytoid cells. The cells were cytokeratin positive (not shown) and nonreactive with lymphoid/plasma cell markers (e.g., CD20, CD79, CD138).

Fig. 24-14. Middle ear adenoma.

A, Middle ear adenoma that perforated the tympanic membrane resulting in a clinical presentation as an external auditory canal lesion; histologically, pagetoid and subepithelial spread of the tumor to the external canal keratinizing squamous epithelium is present. **B,** Given the limited anatomic confines of the middle ear space, middle ear adenomas, as well as other benign middle ear tumors, may have expansive growth including into connective tissue structures; the presence of perineural growth, as seen in this illustration, in an otherwise benign-appearing neoplasm may occur in middle ear adenomas and should not be misinterpreted as a malignancy; additional findings are needed to diagnose a malignancy.

confined to the middle ear space with possible extension to the mastoid; occasionally, the adenoma will perforate through the tympanic membrane with extension into and presentation as an external auditory canal mass.

- No known etiologic factors related to the development of MEA:
 - Not associated with a prior history of chronic otitis media
 - Concurrent cholesteatomas may be seen but there is no known association between these two lesions.
- Radiologic imaging:
 - In its more typical radiologic presentation, appears as a relatively avascular soft tissue density without evidence of destructive, invasive, or erosive properties.

Pathology

Gross

- Gray-white to red-brown, rubbery to firm mass free of significant bleeding on manipulation

Histology

- Unencapsulated lesion with glandular or tubule formation, as well as solid, sheetlike, trabecular, cystic and cribriform (back-to-back) growth patterns; rarely, may show a predominant papillary growth
- Glands are composed of:
 - Single layer of cuboidal to columnar cells with a varying amount of eosinophilic cytoplasm
 - Round to oval nuclei; nucleoli may be seen and are generally eccentrically located

- Nuclear chromatin ranges from densely packed (hyperchromatic) to a more dispersed “salt and pepper” pattern
- Cells typically lack presence of cilia
- Cells often have a prominent plasmacytoid appearance, particularly evident in the more solid areas of growth but also in the cells forming the glandular structures
 - Paranuclear clear zone is not present.
- Cellular pleomorphism may be prominent but mitoses are uncommon.
- Rarely, perineural invasion may occur; in the absence of cytomorphic features of malignancy (see later discussion under middle ear adenocarcinoma) neurotropism is not evidence of malignancy.
- Stromal component is sparse and may appear fibrous or myxoid.
- Histochemistry:
 - Intraluminal but not intracytoplasmic mucin-positive material may be seen.
 - PAS-positive material is not identified.
 - Neoplastic cells may be argentaffin (Fontana stain) and argyrophilic (Churukian-Schenk) positive.
- Immunohistochemistry (see Chapter 25, Table 25-1):
 - Cytokeratins and epithelial membrane antigen are consistently positive:

- AE1/AE3, CAM 5.2, and CK7 are diffusely positive.
- Focal and weak CK20 reactivity may be seen.
- CK5/6 may be present.
- p63 may be present.
- S100 protein, smooth muscle actin negative:
 - Suggests absence of myoepithelial cells in MEA
- Neuroendocrine differentiation may be seen (see below) as identified by the presence of synaptophysin, chromogranin, CD56, and neuron-specific enolase.
- Serotonin and human pancreatic polypeptide also may be present.
- Vimentin staining may be present.
- Desmin and actin are negative.

Middle Ear Adenoma with Neuroendocrine Differentiation (Fig. 24-15)

- MEAs may show neuroendocrine features by light microscopic and immunohistochemical staining, including:
 - Ribbons, cord-like, and organoid growth patterns
 - Cells with dispersed or stippled-appearing (“salt and pepper”) nuclear chromatin

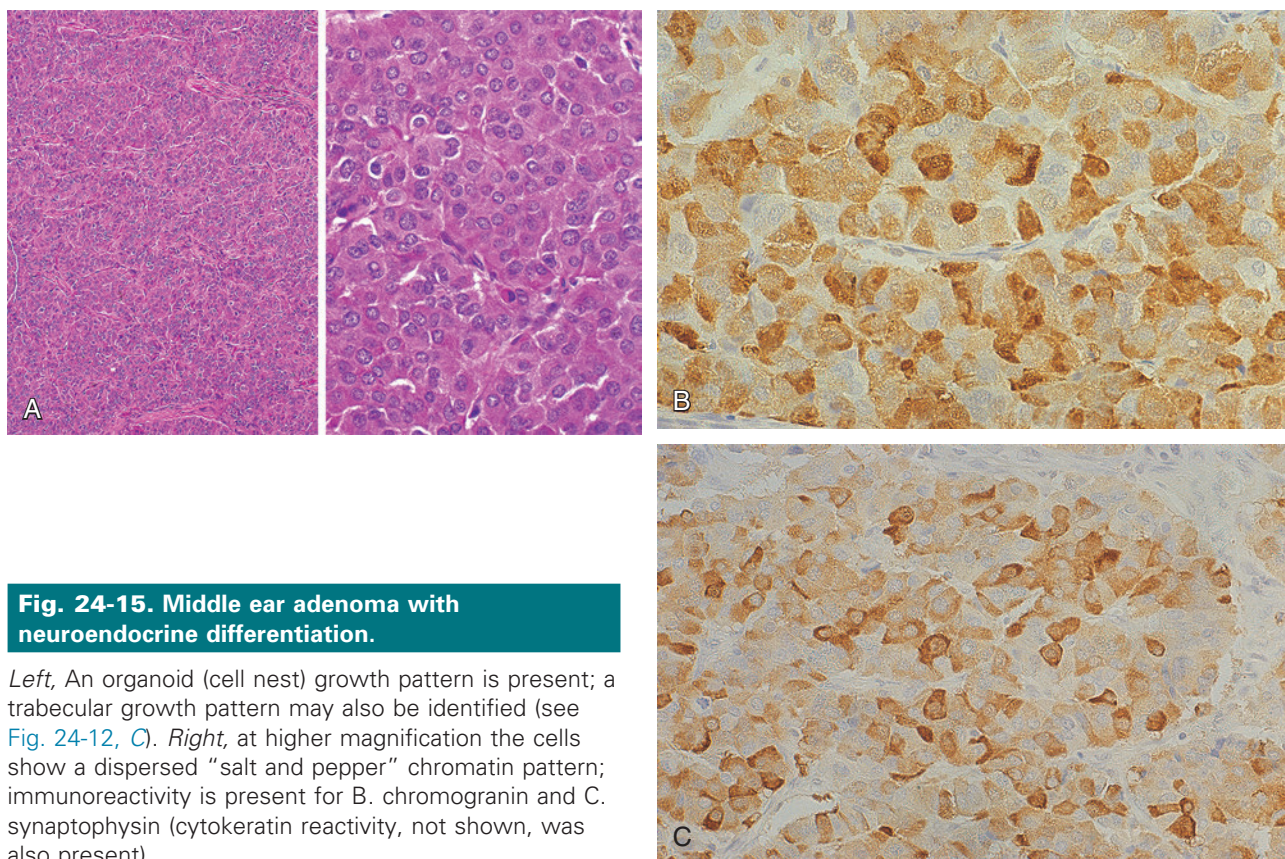

Fig. 24-15. Middle ear adenoma with neuroendocrine differentiation.

Left, An organoid (cell nest) growth pattern is present; a trabecular growth pattern may also be identified (see Fig. 24-12, C). *Right*, at higher magnification the cells show a dispersed “salt and pepper” chromatin pattern; immunoreactivity is present for B. chromogranin and C. synaptophysin (cytokeratin reactivity, not shown, was also present).

- Immunoreactivity with one or more neuroendocrine markers, including synaptophysin, chromogranin, CD56, NSE:
 - Serotonin and human pancreatic polypeptide also may be present.
 - Despite the presence of vasoactive compounds in these tumors, carcinoid syndrome is extraordinarily rare in association with these neoplasms.
- MEAs with neuroendocrine differentiation have been termed carcinoid tumors of the middle ear as well as neuroendocrine adenoma of the middle ear (NAME).
- The issue relative to these tumors is whether they be classified as MEA with neuroendocrine differentiation or carcinoid tumor (also referred to as well-differentiated neuroendocrine carcinoma):
 - Controversy relates to their biologic behavior:
 - Locally recurrent tumor (which may be a function of inadequate initial excision) or regional metastasis have been reported, which support the contention that at least some of these middle ear neoplasms are carcinoid tumors/well-differentiated neuroendocrine carcinomas
 - However, long-term follow-up shows the overwhelming majority of these tumors have a benign biologic course, supporting the contention that these neoplasms are best viewed as being part of the histologic spectrum of MEA, albeit with neuroendocrine differentiation.
 - Presence of chromogranin-positive cells within hyperplastic but not in nonneoplastic middle ear epithelium overlying an MEA supports the inclusion of middle ear glandular tumors with neuroendocrine differentiation within the spectrum of MEA.

Middle Ear Adenoma with Papillary Features (Aggressive Papillary Tumor)

- Another controversial issue relative to MEAs is the presence of papillary growth and whether such papillary middle ear neoplasms represent part of the histologic spectrum of MEAs or whether such tumors in reality are endolymphatic sac papillary tumors (ESPTs).
- Unlike ESPTs, MEAs typically lack papillary architecture and are not associated with evidence of bone destruction:
 - When confronted with a tumor of the middle ear and temporal bone with papillary architecture and destructive growth, the likely diagnosis is that of ESPT, a neoplasm that often is associated with von Hippel-Lindau syndrome (VHL).
 - However, there are documented cases of MEAs with papillary growth confined to the middle ear

space, including the eustachian tube, without destructive growth:

- Such findings support the existence of a middle ear neoplasm with papillary growth originating from the middle ear, occurring sporadically without association to VHL and representing a distinct variant of MEA unrelated to ESPT.

Differential Diagnosis

- Metaplastic glandular proliferation secondary to otitis media:
 - Glandular metaplasia may occur in the setting of chronic otitis media (COM).
 - Metaplastic glands may be misdiagnosed as neoplastic.
 - In contrast to MEA, the glandular proliferation in COM is focal identified or haphazardly arrayed and occurs in the presence of histologic features of COM, including chronic inflammation with fibrosis and calcifications (tympanosclerosis).
 - Identification of cilia supports a diagnosis of metaplastic glands rather than an adenoma.
- Ceruminous gland adenoma:
 - MEAs may perforate the tympanic membrane and appear to represent a neoplasm of the external auditory canal, such as a ceruminous gland adenoma.
 - Histologic features of ceruminous gland adenoma are distinctly different from MEA, including the presence of decapitation-type secretion and intracytoplasmic cerumen.
- Differential diagnosis of MEA is primarily with the other more common middle ear tumors, including jugulotympanic paraganglioma, meningioma, and acoustic neuroma. The pathologic features of these other tumor types are discussed below.
- Endolymphatic sac papillary tumor (ESPT):
 - Occasional MEAs have a predominant papillary architecture.
 - See previous discussion under Middle Ear Adenoma with Papillary Features (Aggressive Papillary Tumor).
 - There is some confusion in the literature regarding these papillary MEAs and their relationship to the endolymphatic sac papillary tumor; as discussed later in this chapter, the histogenesis, clinical presentation, anatomic location, pathologic features, and clinical course of ESPT are decidedly different from MEA.
- Middle ear adenocarcinoma:
 - In contrast to the rare middle ear adenocarcinoma, MEAs lack marked cellular pleomorphism, increased mitotic activity, necrosis or invasion of bone, and other soft tissue structures.
- Rhabdomyosarcoma

Treatment and Prognosis

- Complete surgical excision is the preferred treatment:
 - Surgery may be conservative if the lesion is small and confined to the middle ear or more radical (mastoidectomy) for larger lesions associated with more extensive structural involvement.
- Recurrence may occur and is usually a function of inadequate excision.
- Some MEAs may be locally aggressive and rarely may invade vital structures, causing death.
- In general, the clinical, radiologic, and pathologic findings indicate that the tumor is benign (absence of associated neural deficits, invasion or destruction of adjacent structures, or pleomorphism and increased mitotic activity); nevertheless, the histologic appearance is not always predictive of the clinical behavior.

JUGULOTYMPANIC PARAGANGLIOMA (JTP)

(Figs. 24-16 through 24-21)

Definition: Benign neoplasm arising from the extra-adrenal neural crest–derived paraganglia specifically located in the middle ear or temporal bone region.

Synonyms: Glomus jugulare tumor; glomus tympanicum tumor

Clinical

- Arguably, considered the most common tumor of the middle ear
- Affect women more than men; most commonly seen in the fifth through seventh decades of life
- Jugulotympanic paragangliomas occur in one of three locations:
 - 85% arise in the jugular bulb (*glomus jugulare tumor*), resulting in a mass lesion in the middle ear or external auditory canal.
 - 12% originate in the posterior auricular branch of the vagus nerve, also known as Arnold's nerve (*glomus tympanicum tumor*), presenting in the middle ear.
 - 3% originate from the tympanic branch of the glossopharyngeal nerve, also known as Jacobson's nerve (*glomus tympanicum tumor*), presenting as a mass in the external auditory canal.
- Most common symptom is conductive hearing loss; other symptoms include tinnitus, fullness, otic discharge, pain, hemorrhage, facial nerve abnormalities, and vertigo.
- Often are locally invasive neoplasms with extension into and destruction of adjacent structures, including the temporal bone and mastoid

- Radiology:
 - CT scan: soft tissue mass often with evidence of extensive destruction of adjacent structures
 - Carotid angiography: vascularized lesion fed by branches of nearby large arteries
 - MR imaging: in tumors larger than 2 cm there is a unique salt-and-pepper pattern of hyperintensity and hypointensity on T1-weighted and T2-weighted imaging.
- Familial (hereditary) paraganglioma:
 - JTPs may be familial (hereditary)
 - Familial JTPs may be multifocal, including jugulotympanic and carotid body.
 - Autosomal dominant pattern of inheritance is favored.
 - Genetic analysis has shown linkage with two different loci, including 11q13.1 and 11q22.3-q23.
 - See Section 4, The Neck, for a more complete discussion.
- Jugular and tympanic paragangliomas have been reported as a single entity (i.e., temporal bone paragangliomas) but their distinction has important clinical and therapeutic implications; as such, classification schemes based on site of origin (Table 24-2) or based on site and origin and extent of tumor involvement have been developed (Table 24-3).

Pathology

Gross

- Polypoid, red, friable mass identified behind an intact tympanic membrane or within the external auditory canal, measuring from a few millimeters to a large mass completely filling the middle ear space
- Typically, paragangliomas bleed profusely on manipulation.

Histology

- Histologic hallmark is the presence of a cell nest, or “zellballen,” pattern characteristic of paragangliomas:
 - Although this pattern is characteristic of paragangliomas, it is not unique to paragangliomas and can be seen in other neuroendocrine tumors, including carcinoid and atypical carcinoid tumors, as well as in middle ear adenoma, carcinomas, and melanoma.
- Stroma surrounding and separating the nests is composed of a prominent fibrovascular tissue.
- Neoplasm is composed of chief cells and sustentacular cells:
 - Chief cells predominate and include round or oval with uniform nuclei, dispersed chromatin pattern, and abundant eosinophilic, granular, or vacuolated cytoplasm.
 - Sustentacular cells represent modified Schwann cells and are situated at the periphery of the cell

Fig. 24-16. Glomus jugulare tumor CT.

A, Axial image shows demineralization of the bony margins of the jugular foramen on the right (*black arrows*). There is demineralization of the fine cortical line usually demonstrated along the lateral aspect of the vascular portion of the jugular foramen. Compare with the intact cortical plate on the opposite side (*white arrow*). Note the demineralization of the bony wall separating the carotid canal from the jugular foramen. **B**, Blown-up axial image shows demineralization of the lateral cortical plate (*arrowhead*), as well as slight demineralization of the bony plate between the carotid canal and the jugular foramen (*white arrow*). Note the proximity of the demineralized bone to the vertical section of the facial nerve canal (*white arrow*). **C**, Axial image enlarged through the normal side shows the intact white cortical line (*arrow*) along the lateral aspect of the jugular foramen. The integrity of this line essentially excludes a glomus jugulotympanicum tumor. **D**, Coronal image shows demineralization of the margins (*arrowheads*) as well as the soft tissue of the intratympanic portion of the tumor (*arrow*). (Courtesy Dr. Hugh D. Curtin. From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 20-120, p 1329)

Fig. 24-17. Carotid angiogram of jugulotympanic paraganglioma.

A, Glomus tympanicum tumor. Selective external carotid angiogram. Characteristic hypervascularity (*arrow*) is seen.
B, Glomus jugulare tumor. Selective external carotid angiogram. The characteristically hypervascular tumor is supplied by the hypertrophic ascending pharyngeal artery (*arrow*). Note the early draining vein (*arrowhead*) seen during the midarterial phase. Differential diagnosis includes other hypervascular tumors such as metastatic renal cell carcinoma, metastatic pheochromocytoma, myeloma, and so on. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Figs. 20-124 and 20-125, p 1331.)

Fig. 24-18. Jugulotympanic paraganglioma.

Jugulotympanic paraganglioma characterized by a bright red polypoid mass originating in the middle ear space.

nests, appearing as spindle-shaped, basophilic cells.

- Are difficult, if not impossible, to identify by light microscopy alone, requiring S100 protein staining for identification
- No glandular or alveolar differentiation is seen.
- Cellular pleomorphism can be seen; mitoses and necrosis are infrequently identified.
- Spindling of the chief cells may be seen and infrequently may predominate.
- Not infrequently, jugulotympanic paragangliomas do not display the characteristic cell nest or organoid growth but appear compressed due to artifactual distortion secondary to surgical manipulation (“squeezing”) of the tissue during removal:
 - In addition to the loss of an organoid pattern of growth, jugulotympanic paragangliomas may be

Fig. 24-19. Jugulotympanic paraganglioma.

A, Jugulotympanic paraganglioma showing characteristic histologic appearance including the presence of a cell nest (organoid) growth pattern separated by fibrovascular stroma. **B**, Higher magnification shows the tumor to be predominantly composed of chief cells, which are round or oval with uniform nuclei, dispersed chromatin pattern, and abundant eosinophilic, granular, or vacuolated cytoplasm; the peripherally located sustentacular cells are difficult to identify by light microscopy and appear as spindle-shaped cells with a basophilic appearance. Immunohistochemical confirmation of paraganglioma includes the presence of immunoreactivity for neuroendocrine markers, with **(C)** diffuse synaptophysin (and chromogranin, not shown) reactivity and **(D)** S100 protein staining highlighting the peripherally situated sustentacular cells.

- associated with a dense fibrous stroma and an appearance of infiltrative growth.
 - These findings may result in overlooking a diagnosis of JTP, resulting in an erroneous interpretation including other benign middle ear neoplasms or even a malignant neoplasm.
 - Awareness of this occurrence and use of appropriate special stains should allow for a correct diagnosis.
- Histochemistry:
 - Reticulin staining may better delineate the cell nest growth pattern with staining of the fibrovascular cores surrounding the neoplastic nests.
 - Tumor cells are argyrophilic (Churukian-Schenk).
 - Argentaffin (Fontana), mucicarmine, and periodic acid-Schiff stains are negative.
- Immunohistochemistry (see Chapter 25, Table 25-1):
 - Chief cells: synaptophysin, chromogranin, CD56, neuron-specific enolase, neurofilaments, and a variety of peptides positive
 - Sustentacular cells: S100 protein and SOX10 positive:
 - Characteristic peripheral pattern for staining correlating to the location of the sustentacular cells
 - Vimentin is variably reactive in the chief cells and sustentacular cells.
 - In general, epithelial markers, including cytokeratins, as well as HMB-45 and mesenchymal markers (desmin and other markers of myogenic differentiation), are negative; rare examples of cytokeratin-reactive paragangliomas have been reported.

- Electron microscopy:
 - The hallmark of the EM findings is the presence of neurosecretory granules.

Differential Diagnosis

- Middle ear adenoma with or without neuroendocrine differentiation
- Acoustic neuroma
- Meningioma

Fig. 24-20. Jugulotympanic paraganglioma.

A, The histologic appearance of jugulotympanic paragangliomas can be distorted or masked secondary to artifactual changes, but the characteristic cell nest appearance is usually focally maintained and **(B)** reticulin staining is helpful in delineating the cell nest growth by staining the fibrovascular stroma surrounding the tumor nests.

Treatment and Prognosis

- Complete surgical excision is the preferred treatment:
 - Paragangliomas confined to the middle ear (Glasscock-Jackson type I; Fisch class A) can be approached through a transcanal approach.
 - If the margins of tumor are not discernible but the bone over the jugular bulb and the carotid canal is intact (i.e., Glasscock-Jackson types II and III, Fisch class B), a postauricular transmastoid approach and extended facial recess approach provides excellent exposure for tumor resection.
 - Involvement of the jugular bulb requires a combined transmastoid and transcervical approach.
 - Limited involvement of the jugular bulb without carotid artery involvement requires a complete mastoidectomy and an extended facial recess approach.
 - More extensive involvement of the jugular bulb or involvement of the intrapetrous internal carotid artery requires an infratemporal fossa approach.
- Preoperative embolization has been advocated as useful to decrease the vascularity of the tumor and allow for safer surgery:
 - Main objective is to direct the embolism material to selectively permeate only the vascularity of the paraganglioma without proximal occlusion of the feeding artery and also avoiding distal migration of emboli into the systemic circulation.
 - Postembolization angiography should document absence of tumor “blush” with continued patency of the external carotid systems.

Fig. 24-21. Jugulotympanic paraganglioma.

A and **B**, Another example of a jugulotympanic paraganglioma in which tumor nests show an “invasive” growth with associated dense fibrotic stroma; the absence of discrete cell nest growth pattern is associated with extensive fibrosis. These findings, especially when coupled to radiographic evidence of bone erosion, may result in the erroneous interpretation as a malignant neoplasm. Immunohistochemical stains assist in the diagnosis as evidenced by

**Fig. 26-21, cont'd**

(C) synaptophysin and (D) S100 protein immunoreactivity, the latter limited to the peripherally located sustentacular cells.

TABLE 24-2 Fisch Classification of Jugulotympanic Parangliomas

Class A	Tumors arising along the tympanic plexus on the middle ear promontory
Class B	Tumors arising from the inferior tympanic canal of the hypotympanum; may invade the middle ear and mastoid; cortical bone over jugular bulb is intact; carotid canal is intact
Class C	Tumors arising in dome of jugular bulb and involving the overlying cortical bone
C1	Tumors eroding the carotid canal but not involving the carotid artery
C2	Tumors involving the vertical carotid canal
C3	Tumors involving the horizontal carotid canal; foramen lacerum is free of tumor
C4	Tumors involving the foramen lacerum and the cavernous sinus
Class D	Tumors with intracranial extension of posterior fossa
De1	Extradural tumor of less than 2 cm medial dural displacement
De2	Extradural tumor of more than 2 cm medial dural displacement
Di1	Intradural tumor of less than 2 cm
Di2	Intradural tumor of more than 2 cm
Di3	Neurosurgically unresectable tumor

TABLE 24-3 Glasscock-Jackson Classification of Glomus Tumors

Glomus Tympanicum	
Type I	Small mass limited to promontory
Type II	Tumor completely filling the middle ear space
Type III	Tumor filling the middle ear and extending into the mastoid
Type IV	Tumor filling the middle ear, extending into the mastoid or through the tympanic membrane to fill the external auditory canal; may also extend anterior to the internal carotid artery
Glomus Jugulare	
Type I	Small tumor involving the jugular bulb, middle ear, and mastoid
Type II	Tumor extending under the internal auditory canal; may have intracranial extension
Type III	Tumor extending into petrous apex; may have intracranial extension
Type IV	Tumor extending beyond the petrous apex into the clivus or infratemporal fossa; may have intracranial extension

- Experienced vascular radiology team must be thoroughly familiar with the complexities and possible variations in head and neck vascular anatomy.
- Not all paragangliomas should be embolized:
 - Decision is dependent on the location and extent of tumor and the experience of the surgeon and interventional radiologist.
 - Paragangliomas confined to the middle ear cavity do not require preoperative

embolization if the patient is being treated by an experienced otologic surgeon.

- Other types of paragangliomas can be treated by preoperative embolization.
- Location and invasive nature of these lesions often preclude the capability of complete surgical eradication, and in such situations radiotherapy is a useful adjunct to surgery:
 - Unresectable paragangliomas include those with extensive skull base involvement or intracranial extension.
 - Patients who might be poor surgical candidates, including medically infirm and elderly
 - Radiotherapy results in a decrease or ablation of vascularity and promotes fibrosis.
 - Radiotherapy has been used primarily to treat jugular paragangliomas of the temporal bone.
 - Because there is rarely total resolution of the tumor following radiotherapy, successful treatment of paragangliomas with radiotherapy is defined as local control in the form of stability or regression of tumor size and nonprogression or improvement of neurologic symptoms.
- Local recurrence of the tumor can be seen in as many as 50% of the cases.
- Although these are slow-growing neoplasms, prognosis is guarded because they often infiltrate and invade adjacent structures.
- Although malignancy is rare, these neoplasms may result in increased morbidity and mortality as a result of invasion of vital structures (e.g., cranial cavity).
- Histologic appearance of paragangliomas does not correlate to the biologic behavior of the tumor.
 - JTPs are slow-growing tumors but may be locally invasive with extension into and destruction of adjacent structures, including the temporal bone and mastoid.
 - Intracranial extension may occur in up to 15% of cases.
- Neurologic abnormalities, including cranial nerve palsies, cerebellar dysfunction, dysphagia, and hoarseness, may be seen and correlate to the invasive capabilities of this neoplasm.
- Functioning JTPs as evidenced by endocrinopathic manifestations occur but are extremely uncommon.
- Malignant JTPs occur and are associated with histologic criteria of malignancy, including:
 - Increased mitotic activity
 - Necrosis usually seen within the center of the cell nests
 - Vascular invasion
 - Metastasis to cervical lymph nodes, lungs, and liver
- In general, DNA ploidy studies by image analysis are not predictive of the behavior of paragangliomas.

ACOUSTIC NEUROMA (AN)

(Figs. 24-22 through 24-24)

Definition: Benign neoplasm arising from Schwann cells specifically originating from the eighth cranial nerve.

Synonyms: Acoustic schwannoma; benign peripheral nerve sheath tumor; neurilemmoma

Clinical

- Account for up to 10% of all intracranial neoplasms and for up to 90% of all tumors of the cerebellopontine angle
- More common in women than in men; may occur at any age but are most common in the fourth to seventh decades of life
- Majority involve the superior or vestibular portion of the eighth nerve as compared with involvement of the cochlear portion of the eighth nerve.
- Typically develop at the neuroglial-neurolemmal junction termed the Rednik-Obersteiner line identified immediately inside the meatus of the internal auditory canal; however, the site of this junction varies and so too does the site of acoustic neuromas.
- Symptoms include progressive (sensorineural) hearing loss, tinnitus, and loss of equilibrium; with

Fig. 24-22. Acoustic neuroma.

Axial CT air cisternogram of acoustic neuroma: intrathecally injected air outlines a left intracanalicular tumor (arrows), which extends into the cerebellopontine angle. The left internal auditory canal (arrowheads) is slightly enlarged, a typical feature of eighth nerve schwannomas. MR imaging has virtually replaced invasive diagnostic techniques.

Fig. 24-23. Acoustic neuroma.

Coronal MR T1-weighted image, enhanced, of an acoustic neuroma: contrast-enhanced tumor (*arrow*) largely confined by the right internal auditory canal. Contrast-enhanced MR is now the preferred imaging modality for evaluation of neurosensory hearing loss and suspected cerebellopontine angle masses.

progression the tumor enlarges and may compress adjacent cranial nerves (V, VII, IX, X, XI), the cerebellum and the brainstem leading to facial paresthesia and numbness, headaches, nausea, vomiting, diplopia, and ataxia.

- Up to 8% may be bilateral; bilaterality is a potential marker of neurofibromatosis type 2 (NF-2):
 - NF-2 is an autosomal-dominant condition.
 - Gene for NF-2 mapped to the long arm of chromosome 22 (22q12)
 - Hallmark of NF-2 is bilateral acoustic neuromas.
 - Patients with NF-2 have an increased incidence of developing a meningioma.
 - Patients with acoustic neuroma (or meningioma) who are under 30 years of age should raise concern for a diagnosis of NF-2:
 - Seen in more than 90% of patients with NF-2
 - Accounts for approximately 5% of all vestibular neuromas
 - Symptoms of neurofibromatosis may be seen in up to 16% of patients and those with neurofibromatosis who develop acoustic neuromas generally are symptomatic at an earlier age (teenage years or early third decade of life) and

have a higher incidence of bilateral acoustic neuromas.

- Symptoms include:
 - Early: hearing (sensorineural) loss, tinnitus, dizziness
 - Late: headache, facial pain and/or weakness, others
- Occasionally, unilateral vestibular (acoustic) neuroma may occur in patients with NF-2 in the absence of other criteria necessary for a diagnosis of NF-2.
- Approximately 50% to 67% of patients with NF-2 develop cutaneous schwannomas.
- Patients with NF-2 also experience increased incidence of multiple, separately occurring meningiomas in intra- and extracranial meningiomas.
- Radiology:
 - CT and MRI: flaring, asymmetric widening, or erosion of the internal auditory canal; these techniques are capable of detecting tumors with dimensions of 1 cm and less.

Pathology

Gross

- Unilateral, circumscribed, tan-white, rubbery to firm mass, which may appear yellow and have cystic change
- Sizes range from a few millimeters up to 4 to 5 cm in greatest diameter.

Histology

- Unencapsulated tumors are composed of alternating regions composed of compact spindle cells (so-called Antoni A areas), and loose, hypocellular zones (so-called Antoni B areas); in a given tumor, the proportion of these components varies.
- Cells are arranged in short, interlacing fascicles and whorling or palisading of nuclei may be seen:
 - Nuclear palisading with nuclear alignment in rows are called Verocay bodies.
- Nuclei are vesicular to hyperchromatic, elongated, and twisted with indistinct cytoplasmic borders.
- Antoni B areas display a disorderly cellular arrangement, myxoid stroma, and a chronic inflammatory cell infiltrate.
- Increased vascularity is prominent, composed of large vessels with thickened (hyalinized) walls.
- Mitoses, usually sparse in number, and cellular pleomorphism with hyperchromasia can be identified but are not evidence of malignancy.
- Cellularity may vary and some benign schwannomas can be very cellular, conferring the name cellular schwannoma.
- Retrogressive changes may be present, including cystic degeneration, necrosis, hyalinization, calcification, and hemorrhage.

Fig. 24-24. Acoustic neuroma.

A, Acoustic neuroma is unencapsulated and composed of central cellular zone of spindle-shaped cells (Antoni A areas) and loose, hypocellular zones (Antoni B areas) along the outer aspects. **B**, Fascicular growth of spindle-shaped cells; vascular hyalinization is seen. **C**, The cellular component includes elongated and twisted (buckled or wavy) nuclei with indistinct cytoplasmic borders. **D**, Nuclear palisading (Verocay bodies) may be seen. **E**, Degenerative changes including perivascular hyalinization (*left*) and foamy histiocytes (*right*) may be present. **F**, Diffuse and intense S100 protein immunoreactivity is characteristically present.

- Immunohistochemistry (Chapter 25, Table 25-1):
 - Diffuse and intense S100 protein positivity
 - SOX10 immunoreactivity:
 - Transcription factor involved in neural crest development and differentiation of neural crest cells into melanocytic and schwannian differentiation
 - Sensitive marker for melanoma:
 - ◻ Diffuse and strong nuclear staining
 - ◻ Expression reported in more than 85% to 90% of melanomas
 - Reactivity also present in:
 - ◻ Schwannomas (100%)
 - No immunoreactivity for cytokeratins or the neuroendocrine markers chromogranin and synaptophysin
 - Most common sites of occurrence of the ectopically located meningiomas is the head and neck region, including:
 - Middle ear and temporal bone (internal auditory canal, jugular foramen, geniculate ganglion, roof of the eustachian tube, sulcus of the greater petrosal nerve)
 - Sinonasal cavity
 - Orbit, oral cavity, and parotid gland
 - Symptoms vary according to site and in the middle ear and temporal bone area clinically simulate an acoustic neuroma with symptoms including progressive loss of hearing, loss of equilibrium, headaches, cerebellar dysfunction, and cranial nerve abnormalities
 - May be associated with neurofibromatosis type (NF-2):
 - Patients with NF-2 have an increased incidence of developing a meningioma.
 - Patients with NF-2 also experience increased incidence of multiple, separately occurring meningiomas in intra- and extracranial meningiomas.
 - The hallmark of NF-2 is bilateral acoustic neuromas.
 - Patients with an acoustic neuroma or meningioma who are under 30 years of age should raise concern for a diagnosis of NF-2.
 - Radiologic findings include:
 - Soft tissue mass with variable vascularity
 - A feature that correlates to the histology and is considered a pathognomonic feature for meningioma in this location is the presence of speckled calcification in a soft tissue mass.

Differential Diagnosis

- Middle ear adenoma
- Jugulotympanic paraganglioma
- Meningioma

Treatment and Prognosis

- Complete surgical excision is the preferred treatment and is curative.
- Alternative nonmicrosurgical treatment (i.e., radiotherapy) for smaller tumors may play an increasingly important role in the future.
- Death may occur secondary to herniation of the brainstem in untreated and/or large neoplasms.
- Malignant AN (malignant peripheral nerve sheath tumors) are exceedingly rare and, if present, neurofibromatosis should be suspected.

MENINGIOMA (Figs. 24-25 and 24-26)

Definition: Benign neoplasms arising from arachnoid cells forming the arachnoid villi seen in relation to the dural sinuses.

Clinical

- Represent 13% to 18% of all intracranial tumors
- Represent the second most common tumor of the cerebellopontine angle
- More common in women than in men; occur over a wide age range but are most commonly seen in the fifth decade of life and infrequently occur in children
- Occurrence outside the central nervous system is considered ectopic and is divided into:
 - Primary meningioma with no identifiable CNS connection
 - Secondary meningioma with CNS connection
- Development of meningiomas in the middle ear and temporal bone results either by direct extension or from the presence of arachnoid cells ectopically located.

Pathology

Gross

- Lobular-appearing, tan-white to gray, rubbery to firm mass with a gritty consistency
- In contrast to their intracranial counterparts, which are well-delineated and circumscribed lesions, meningiomas of the middle ear tend to be infiltrative with extension and invasion of adjacent structures.

Histology

- Four histologic variants have been described and include:
 - Syncytial or meningothelial
 - Fibroblastic
 - Transitional (combination of syncytial and fibroblastic)
 - Angioblastic
- In the middle ear the most common histologic subtype is the meningothelial type, which has the following features:
 - Lobular growth with tumor nests separated by a variable amount of fibrous tissue

Fig. 24-25. CPA meningioma with intracanalicular extension.

A and B, T1-weighted images before and after contrast enhancement. Typical hemispheric meningioma with intracanalicular extension. The meningioma is eccentric to the IAC, has a broad dural base, and the cisternal component forms an obtuse angle with the posterior border of the petrous bone. The dural tail of the tumor extending posteriorly is best seen on the post-contrast-enhanced image. **C,** The tumor is homogeneously isointense to gray matter. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 20-22, p 1276.)

- Cells have a whorled appearance and are composed of round to oval or spindle-shaped nuclei with pale staining cytoplasm and indistinct cell borders.
- Characteristically, the nuclei have a punched-out or empty appearance resulting from intranuclear cytoplasmic inclusions.
- Psammoma bodies, typical and numerous in intracranial meningothelial meningiomas, may be seen but are not as often found in meningiomas occurring in the middle ear region.
- Mild cellular pleomorphism may be seen; mitoses are uncommon.
- Immunohistochemistry (see Chapter 25, Table 25-1):
 - Immunoreactivity with vimentin and epithelial membrane antigen (EMA)
 - Typically S100 protein negative but occasionally may be positive, particularly in the fibroblastic variant
 - Cytokeratins can be positive:
 - As a whole may be positive in 20% of cases
 - May approach 40% positivity in epithelial variants
 - D2-40 (podoplanin) positive in majority of cases
 - Neuroendocrine markers (i.e., chromogranin, synaptophysin, others) negative

Fig. 24-26. Meningioma.

A, The histology of meningioma includes a lobular growth with tumor nests separated by a variable amount of fibrous tissue; psammoma bodies are seen. **B**, The neoplastic cell nests have a whorled appearance and are composed of round to oval nuclei with pale staining cytoplasm and indistinct cell borders; characteristically, the nuclei have a punched-out or empty appearance resulting from intranuclear cytoplasmic inclusions; immunoreactivity is present from **C**. Epithelial membrane antigen (EMA) and **(D)** vimentin.

- Low proliferation rate (usually less than 3%) by Ki67 (MIB1) staining

Differential Diagnosis

- Middle ear adenoma
- Jugulotympanic paraganglioma
- Acoustic neuroma

Treatment and Prognosis

- Complete surgical excision is the preferred treatment and is curative.
- Local recurrence relates to inadequate excision.
- Malignant change rarely, if ever, occurs.
- A diagnosis of middle ear meningioma should be made only after clinical evaluation to exclude secondary extension from an intracranial neoplasm.
- There is no correlation between the histologic subtype and clinical behavior, except for the angio-blastic variant, which has been associated with a more aggressive behavior.

OTHER BENIGN TUMORS OF THE MIDDLE EAR AND TEMPORAL BONE (Fig. 24-27)

- Although uncommon, a number of other primary benign tumors can be found in the middle ear or temporal bone.
- Middle ear papillary epithelial neoplasms that are histologically identical to sinonasal or Schneiderian papillomas may rarely be identified:
 - Referred to as Schneiderian-type mucosal papillomas of the middle ear
 - More common in women than in men
 - Occur over a wide age range with an average age of occurrence in the fifth decade of life
 - Presentation may include conductive hearing loss, otalgia, and otorrhea.
 - Often occur in patients with a history of chronic otitis media

Fig. 24-27. Middle ear Schneiderian-type papilloma.

Middle ear papilloma with histologic features of a sinonasal (Schneiderian) type of cylindric cell papilloma.

- Arise de novo without evidence of sinonasal tract papillomas but some have occurred in patients with sinonasal tract papillomas
- Histology identical to that of inverted-type and cylindrical-type Schneiderian papillomas
- Associated squamous cell carcinoma has been reported.
- Complete excision usually necessitating radical tympanomastoidectomy is the preferred treatment.
- Other uncommon primary benign tumors of the middle ear and temporal bone are primarily mesenchymal, including:
 - Hemangiomas, lipoma, osteoma, osteoblastoma, chondroblastoma, and teratomas

MALIGNANT NEOPLASMS OF THE EXTERNAL EAR

BASAL CELL CARCINOMA (BCC) (Figs. 24-28 through 24-30)

Definition: Slow growing, locally infiltrative malignant neoplasm of the skin and subcutaneous adnexal tissue.

Synonym: Basal cell epithelioma

Clinical

- Represents the most common cutaneous malignancy
- More common in men than in women; generally a tumor affecting adults and is most commonly seen in the seventh decade of life
- Sun-exposed areas of the head and neck are the most frequent sites of occurrence:
 - May occur in virtually all cutaneous sites of this region
 - More common locations include the nose, eyelids, nasolabial area, and the auricular area (pinna).
- In general, basal cell carcinomas are asymptomatic; presentation usually occurs because the patient notices a growth.
- Basal cell carcinomas of the external auditory canal are uncommon; however, when this area is involved it typically has extensive subcutaneous involvement, which may not be clinically appreciated.
- Basal cell carcinomas take origin from a pluripotent cell in either the basal cell layer of the surface epithelium or in the epithelium of the subcutaneous adnexae.
- Etiology is related to prolonged sun exposure with resulting actinic damage.
- Basal cell carcinomas may be inherited in the autosomal dominant disorder called nevoid basal cell

carcinoma syndrome (Gorlin syndrome) which includes:

- Autosomal dominant inherited condition with high penetrance and variable expressivity
- Multiple basal cell carcinomas most commonly involving the nose, mouth, eyes, and ear regions
- Occurrence in childhood
- Association with palmar and plantar pitting, odontogenic keratocysts of the jaws, skeletal developmental abnormalities (bifid ribs, brachy-metacarpalism and vertebral anomalies), ectopic calcification in dermal and soft tissue sites, and neurologic abnormalities (mental retardation)
- Caused by mutations in *patched (PTCH)*, a tumor suppressor gene mapped to chromosome 9q22.3q31; in few cases, the syndrome is due to a microdeletion at 9q22.
- Bazex syndrome:
 - Autosomal dominant inherited condition
 - Characterized by:
 - Multiple basal cell carcinomas of the face
 - Follicular atrophoderma
 - Localized or generalized hypohidrosis
 - Hypertrichosis
 - May be associated with other solid malignant neoplasms of varying organs, including those of the head and neck (e.g., squamous cell carcinoma)

Pathology

Gross

- Initially, the lesion is a raised papule or nodule with a waxy or translucent appearance covered by a fine capillary network (telangiectasia).

Fig. 24-28. Basal cell carcinoma.

The clinical appearance of basal cell carcinoma of the external ear may include (A) raised papule or nodule on the helix as well as involving the concha and (B) ulcerated lesions surrounded by raised borders creating a papulonodular ulcerative ("rodent ulcer") lesion on the cutaneous surface behind the ear. (Images courtesy Mark Persky, MD.)

- With time, the central portion ulcerates and is surrounded by raised, pearly appearing borders, creating the typical papulonodular ulcerative lesion referred to as rodent ulcer.

Histology

- Unlike squamous cell carcinoma, basal cell carcinomas do not have a premalignant counterpart.
- Although a variety of histologic growth patterns are identified, all basal cell carcinomas arise in continuity with the basal cell layer of the epithelium or from the adnexae.
- Nodulocystic BCC:
 - Most common histologic type
 - Composed of fairly uniform cells with hyperchromatic, oval or elongated nuclei, scant cytoplasm, and palisading appearance of the nuclei at the periphery of the tumor nests
 - Connected to the overlying epidermis by narrow cords or broad trabeculae
 - Stroma is fibromyxoid and characteristically retracts (separates) from the peripheral portions of the tumor nests.
 - Solar elastosis typically presents in surrounding dermis.
- Various growth patterns include:
 - BCC, solid type:
 - Made up of islands or sheets of tumor cells
 - BCC, morphea-like or sclerosing type:
 - Most frequently occurs on the face, particularly the cheek, forehead, and temples
 - Clinically resembles localized scleroderma
 - Histologically shows tumor cells in elongated strands embedded in a dense, sclerotic stroma

Fig. 24-29. Basal cell carcinoma.

A, Superficial basal cell carcinoma characterized by small nests arising from the basal epidermis. **B**, Nodulocystic BCC arising from the basal epidermis; even at this magnification peripheral nuclear palisading and retraction from surrounding stroma can be seen. **C**, Rounded nests of basaloid cells with peripheral nuclear palisading. **D**, Higher magnification shows the peripheral nuclear palisading characterized by the parallel alignment of the nuclei at the periphery of the tumor nest; note the retraction or separation of the surrounding stroma from the peripheral portions of the tumor nest.

Fig. 24-30. Basal cell carcinoma.

Various types of basal cell carcinoma include (A) Morphea-like (sclerosing) basal cell carcinoma showing conventional basal cell carcinoma in the superficial aspect of the specimen and the invasive component of strands of tumor extending deep into the depth of the dermis and subcutis. B, At higher magnification the morphea-like component is comprised of tumor cells in elongated strands embedded in a dense, sclerotic stroma. C and D, Adenoid basal cell carcinoma in which the tumor islands are arranged in anastomosing cords, creating a lace-like or adenoid pattern. E and F, Metatypical or basosquamous carcinoma composed of a basal cell carcinoma with squamous cell differentiation.

Continued

Fig. 24-30, cont'd

G, Melanin pigmentation in tumor nests may impart a brown-to-black appearance and clinically simulate a malignant melanoma.

- Continuity between the tumor strands and surface epithelium rarely seen
- BCC, adenoid type:
 - Adenoid type in which the tumor islands are arranged in anastomosing cords, creating a lace-like or adenoid pattern
- BCC, keratotic (pilar) type:
 - Composed of keratin microcysts or horn cysts lined by flattened, parakeratotic cells identified within the tumor islands
- Additional histologic variants of basal cell carcinoma include:
 - Metatypical or basosquamous carcinoma:
 - Most often occur on face, in particular ear and nose
 - Composed of a basal cell carcinoma with squamous cell differentiation, less pronounced nuclear palisading, irregular lobules, and more stromal proliferation
 - Basal cell and squamous differentiated tumors lie adjacent to one another or are admixed.
 - Squamous component includes keratinization (individual cell or horn pearl formation) and intercellular bridges.
 - Metastatic rate is similar to squamous cell carcinoma.
- Adamantinoid basal cell carcinoma:
 - Most frequently occurs on face (around eyes and glabella)
 - Histologically composed of stellate basaloid cells, resulting in cribriform pattern
- Keloidal basal cell carcinoma:
 - Simulates a keloid
 - Histologically shows a typical basal cell carcinoma admixed with thick sclerotic collagen bundles
- Pleomorphic basal cell carcinoma:
 - Most often occurs in head and neck
 - Occasionally seen in nevroid basal cell carcinoma syndrome
 - Histologically has typical basal cell carcinoma pattern but includes pleomorphic and multinucleated cells
- Rarely, a sarcomatous histologic variant has been reported (so-called sarcomatoid basal cell carcinoma).
- In any one lesion multiple growth patterns may be identified.
- Cellular pleomorphism, increased mitoses, and necrosis may be seen and vary from case to case.
- Melanin pigmentation may be seen in tumor islands.

Differential Diagnosis

- Adnexal neoplasms:
 - Trichoepithelioma
- Merkel cell carcinoma (see later in chapter):
 - Basal cell carcinoma may coexist with Merkel cell carcinoma.
- Squamous cell carcinoma

Treatment and Prognosis

- Complete surgical excision is the preferred treatment:
 - Given indolent behavior, local excision (e.g., Mohs surgery) provides long-term cure in more than 90% of cases.
 - Similar treatment applicable for even large BCCs.
- Prognosis is excellent following complete excision.
- Local recurrences are not uncommon and are especially high in the morphea or sclerosing type of basal cell carcinoma.
- Metastases are rare except for:
 - Neglected or long-standing tumors that attain large sizes and become deeply and extensively infiltrative

- Basosquamous carcinoma, which for all intents and purposes behaves as a squamous cell carcinoma:
 - Metastatic rates seen in approximately 6% of patients
 - This form of basal cell carcinoma requires a more aggressive surgical approach and a closer follow-up than other types of basal cell carcinomas.
- When metastases occur, spread is usually to regional lymph nodes and to the lungs; metastatic disease is associated with poor prognosis irrespective of any therapeutic intervention.
- Basal cell carcinomas of the external auditory canal are notorious for extensive local invasion and extension to the middle ear, mastoid region, temporal bone, and potentially into the cranial cavity; radical surgical excision may be necessary to eradicate tumors in this location.
- Aside from the metatypical and sclerosing types, histology does not correlate with the biologic behavior.
- Invaluable aid in the diagnosis of squamous cell carcinoma of the external auditory canal, especially in the presence of a well-differentiated squamous epithelial lesion that histologically is bland appearing and may appear to be limited to the auditory canal, belying its invasive nature
- Squamous cell carcinoma of the external auditory canal:
 - CT accurately predicts tumor extent.
 - Evidence of destruction of adjacent structures can be seen, including bone and other soft tissue structures, extension into the middle ear and extradural growth into middle cranial fossa, mastoid involvement, and extension into soft tissues beneath the temporal bone.

Pathology

Gross

- External ear: polypoid, rubbery to firm nodules frequently with ulceration
- External auditory canal: visualization is difficult given the location and concealment by any purulent or hemorrhagic exudates

Histology

- In general, squamous cell carcinomas in this region tend to be well differentiated and composed of infiltrating nests of cells with keratinization (keratin pearl formation, individual cell keratinization) and intercellular bridges:
 - Nuclear atypia is present but it is variable.
 - Increased mitotic activity may be present and may include atypical forms.
 - Frequently, invasive growth is seen, varying from superficial invasion with irregular budding of the basal epithelium from the skin surface to the more obvious invasion characterized by irregular tongues of tumor projecting downward from the surface epithelium and irregular strands of atypical epithelial cells extending between the dermal collagen fibers.
 - Limited tissue sampling as well as tangential sectioning can compromise the ability to definitively identify invasive growth, creating problems in diagnosing carcinoma and differentiating it from benign lesions such as inverted follicular keratosis (see below under differential diagnosis).
- Less differentiated squamous cell carcinomas may occur:
 - Moderately differentiated squamous cell carcinoma usually lacks keratin pearls but does have scattered individual keratinized cells.
 - Poorly differentiated SCC, keratinization is extremely difficult to identify, and classification as SCC is based on features such as associated squamous epithelial dysplasia, a pavement-like

SQUAMOUS CELL CARCINOMA OF THE EXTERNAL EAR AND EXTERNAL AUDITORY CANAL (Figs. 24-31 through 24-34)

Definition: Malignant epithelial tumor arising from the surface epithelium.

Synonym: Epidermoid carcinoma

Clinical

- Accounts for approximately 25% of all squamous cell carcinomas of the head and neck.
- Squamous cell carcinoma of the external ear (i.e., auricular skin):
 - More common in men than in women; most frequently seen in the seventh to eighth decades of life
 - Present with a nonhealing sore
- Squamous cell carcinoma of the external auditory canal:
 - More common in women than in men; most frequently seen in the sixth to seventh decades of life
 - Symptoms mimic those of a chronic otitis media with pain, hearing deficits, and otorrhea (bloody or purulent).
- Suspicion for the presence of a malignancy should be considered in patients with chronic ear infections who suddenly have a change in symptoms, including pain, bleeding, or facial paralysis.
- Usually unilateral but may uncommonly be bilateral
- Radiology:

Fig. 24-31. Squamous cell carcinoma.

The spectrum of clinical appearances of squamous cell carcinoma of the external ear identified in various sites.
(Images courtesy Mark Persky, MD.)

Fig. 24-31, cont'd

- squamoid cellular pattern or foci in which intercellular bridges or some evidence of keratinization is seen.
- Adenoid variant:
 - Unusual variant of SCC with a propensity to occur on the face and scalp and especially on the periauricular area
 - “Adenoid” designation refers to a pseudoglandular appearance that results from tumor cell acantholysis.
 - These tumors have been alternatively referred to as adenoid squamous cell carcinoma, acantholytic squamous cell carcinoma, and adenoacanthoma.
 - Islands of tumor cells show central acantholysis, in which cohesiveness is lost and the tumor cells crumble apart, leaving a relatively intact peripheral rim of more cohesive tumor cells and simulating the presence of a glandular lumen.
 - Acantholytic cells in the false “lumen” often show the deeply eosinophilic cytoplasm that is common in exfoliated dyskeratotic cells.
- Tumor can usually be seen emanating from dysplastic surface epithelium, further supporting its squamous origins.
- Glandlike spaces often contain some amorphous basophilic material; however, histochemically, no evidence of epithelial mucin is found.
- Treatment, prognosis, and grading are the same as conventional squamous cell carcinoma.
- Spindle cell squamous carcinoma:
 - A predominant or exclusive spindle cell morphology may be seen.
 - Spindle cell squamous carcinomas arising on the external ear may:
 - Show little to absent evidence of squamous differentiation (e.g., epithelial dysplasia, carcinoma in situ, infiltrating foci of differentiated squamous cell carcinoma)
 - Frequently have surface ulceration
 - Continuity of the tumor with the overlying epithelium may be seen in those cases not associated with ulceration.

Fig. 24-32. Squamous cell carcinoma.

A, Squamous cell carcinoma appearing as a fleshy polypoid mass protruding from the external auditory canal. **B**, External auditory canal squamous cell carcinoma within the depth of the canal appearing as a gray-white, pearly-appearing polypoid lesion filling the canal. The superficial presentation of these lesions may belie their extensive invasive growth as can be seen in appropriate imaging studies (see next image).

- Infiltrating but demarcated tumor composed of interlacing bundles or fascicular growth pattern
- Histologically composed of cells with elongated hyperchromatic nuclei, cellular pleomorphism with giant cells, increased mitotic activity, including atypical mitoses and a variable amount of amphophilic to eosinophilic cytoplasm
- Heterologous elements including bone and cartilage may be present.
- Immunoreactivity:
 - Cytokeratins (AE1/AE3, CAM5.2, CK5/6, OSCAR), p63, and EMA variably positive:
 - Multiple epithelial markers should be performed in each case to increase potential yield of positive staining;
 - Vimentin invariable positive
 - S100 protein, melanoma markers (HMB-45, melan A, tyrosinase, MART-1 [melanoma antigen recognized by T cells-1], microphthalmia transcription factor [MITF], SOX10) and vascular endothelial markers (CD31, Factor VIII-related antigen, CD34, ERG, Fli1) negative

Differential Diagnosis

- Pseudoepitheliomatous hyperplasia and other reactive hyperplasias
- Cholesteatoma of the external auditory canal
- Seborrheic keratosis and inverted follicular keratoma:
 - Inverted follicular keratosis (IFK): (Fig. 24-35)
 - Variant of seborrheic keratosis
 - Endophytic proliferation of mature squamous epithelium with spongiosis and numerous whorls of eosinophilic flattened squamous cells referred to as squamous eddies; the latter differ from horn cysts by their large number, small size, and circumscription
 - Downward squamous cell proliferation may extend below the adjacent normal epidermis that is typically seen in nonirritated seborrheic keratosis.
 - Inflammation below epithelial proliferation is usually mild or absent, differing from irritated seborrheic keratosis.
 - Diagnostic challenges in differentiation IFK from SCC directly relate to limited tissue sampling.

Fig. 24-33. EAC squamous cell carcinoma.

A and **B**, Axial and coronal CT images in bone algorithm. Tumor fills the EAC lumen. There is destruction of the anterior (arrow in **A**) and superoposterior (arrowheads in **A** and **B**) margins of the EAC. There is extension through the posterior defect to invade the mastoid. **C**, Axial T2-weighted image. The tumor is heterogeneously hypointense to CSF. Note invasion of the mastoid (arrows) by tumor, which can be distinguished from fluid in the mastoid air cells by the tumor's lower signal intensity. **D** and **E**, Pre- and post-contrast-enhanced T1-weighted images, demonstrating enhancement. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia: Elsevier, Fig. 20-199, p 1384.)

Fig. 24-34. Squamous cell carcinoma.

A, Infiltrating well-differentiated squamous cell carcinoma of the external auditory canal originating from the surface epithelium. **B**, Higher magnification shows infiltrating well-differentiated squamous cell carcinoma with keratinization and intercellular bridges. **C**, In some cases, carcinoma in situ or bowenoid dysplasia (Bowen's disease) may be identified. **D**, Adenoid squamous cell carcinoma is a morphologic variant of squamous cell carcinoma that is more often seen in cutaneous rather than mucosal-based squamous cell carcinoma; the adenoid changes represent a degenerative phenomenon. **E**, Spindle cell squamous carcinoma of the external cutaneous skin. The malignant spindle-shaped and pleomorphic cells originate from the surface epithelium (*left*), the latter showing dysplastic changes. The neoplastic cells were immunoreactivity for cytokeratins (AE1/AE3, CAM5.2, OSCAR, CK5/6) and p63 (not shown), confirming the diagnosis.

Fig. 24-35. Inverted follicular keratosis.

Seborrheic keratosis (inverted follicular keratoma) of the external auditory canal. **A**, Polypoid-appearing squamous epithelial proliferation characterized by hyperkeratosis, acanthosis, and horn cysts. **B**, Higher magnification shows an epithelial proliferation composed of squamous cells and basaloid cells. **C**, In the depth of the lesion there is an endophytic proliferation of mature squamous epithelium with squamous eddies.

- Key differentiating feature is the absence (IFK) or presence (SCC) of stromal invasion, which is not as simple to determine in practice as it is in theory:
 - In equivocal cases, identification of lesion extent by radiologic imaging may be the critical determinant in the diagnosis.
 - Tissue sampling including deeper tissues is recommended and may be necessary in rendering a definitive diagnosis.
 - Presumptively, if tissue is sampled from deeper portions of the canal and/or deeper to the lesion itself, then the presence of squamous epithelium even with limited cytologic atypia likely represents well-differentiated squamous cell carcinoma; such epithelium would not be expected to be located in the setting of IFK.
- Atypical fibroxanthoma (see below)
- Malignant melanoma:
 - In general, differentiating squamous cell carcinoma from malignant melanoma is straightforward, but problems may occur in certain circumstances such as in differentiating spindle cell squamous carcinoma from spindle cell malignant melanoma; among the features found in malignant melanoma not identified in carcinoma would be the presence of melanin pigment and immunohistochemical reactivity for S100 protein, HMB45, melan A, tyrosinase, MART-1, MITF and/or SOX10, and absence of epithelial markers.

- Dermatofibrosarcoma protuberans (see below)
- Other sarcomas

Treatment and Prognosis

- External ear:
 - Complete surgical excision is the preferred treatment with or without adjunctive radiotherapy.
 - In general, early detection and complete removal result in good prognosis; however, prognosis depends on the extent of disease and the presence or absence of metastasis.
 - Conservative (limited) local resection can be performed for small lesions limited in extent without osseous invasion or invasion of the middle ear.
 - Some authorities recommended radiotherapy in the treatment of early (T1) lesions.
 - For advanced (higher stage) squamous cell carcinomas, more aggressive management is recommended, including radical surgical resection plus radiotherapy and/or chemotherapy.
 - Elective parotidectomy necessary in advanced SCC:
 - For control of occult parotid node metastasis
 - To secure adequate margins
 - Local recurrence may occur in up to 25% of patients and may correlate to tumor size.
 - Fatal outcomes are seen when tumor has spread beyond the auricle.
- External auditory canal:
 - Complete surgical excision is the preferred treatment:
 - Often requires a radical procedure (mastoidectomy or temporal bone resection)
 - Radiotherapy may be indicated depending on the extent of disease.
 - Prognosis is considered poor with approximately 25% 5-year survival rates.
 - Histologic differentiation does not correlate with prognosis.
 - Squamous cell carcinomas in this location often go undetected for long periods time and presentation is with advanced disease involving the mastoid and/or middle ear.
 - Regional lymph node metastases are seen infrequently, and death is generally attributed to invasion of regional structures, particularly intracranial extension.
 - In general, early detection and complete removal result in good prognosis:
 - 3-year estimated survival for T1 and T2 lesions of 100%
 - 5-year estimated survival for T3 and T4 of 80% and 35%, respectively
 - Prognosis is dependent on the extent of disease (i.e., stage), completeness of surgery with tumor-free margins, recurrence, and metastasis.

- Local recurrence may occur in up to 25% of patients and may correlate with tumor size.
- Owing to the low risk of nodal metastasis occurring in less than 20% of patients, elective neck dissection is not advocated.
- Pathologic factors linked to propensity for local recurrence and metastases include:
 - Carcinomas measuring greater than 2 cm in diameter, greater than 4 mm in depth
 - Perineural invasion
 - Development within a scar
 - Previously treated squamous carcinoma in the site
 - Host immunosuppression
 - Histologic differentiation does not necessarily correlate with prognosis.
- Death is generally attributed to invasion of regional structures, particularly intracranial extension.
- On the basis of clinical radiographic-histopathologic correlation, a TNM staging system for external auditory meatus carcinoma (referred to as the Pittsburgh classification system) was proposed (Table 24-4), using preoperative computed tomography and physical examination:
 - 2-year determinant survival in this classification includes:
 - Stage I (T1N0): 100%
 - Stage II (T2N0): 80%
 - Stage III (T3N0M0, T1 or T2 or T3N1M0): 50%

TABLE 24-4 TNM Staging System for External Auditory Meatus Carcinoma (Pittsburgh Classification System)

Stage	Status
T1	Tumor limited to EAM without bony erosion or evidence of soft tissue extension
T2	Limited EAM erosion (not full thickness), or radiographic findings consistent with limited (<5 mm) soft tissue involvement
T3	Erosion into the EAM (full thickness) with limited (<5 mm) soft tissue involvement, or tumor involving the middle ear and/or mastoid, or presence of facial paralysis
T4	Tumor eroding the cochlea, petrous apex, medial wall of middle ear, carotid canal, jugular foramen or dura, or with extensive (>5 mm) soft tissue involvement
N	As described by the American Joint Committee for classifying lymph node involvement in head and neck neoplasms. However, any node involvement is considered to be advanced disease: stage III, T1, N1; stage IV, T2, T3, T4, N1
M	Any metastasis is considered to be advanced disease: stage IV, M1

EAM, External auditory meatus.

Data from Gaudet et al: Applicability of the Pittsburgh Staging System for advanced cutaneous malignancy of the temporal bone, *Skull Base*, 20(6):409–441, 2010.

TABLE 24-5 T Staging of Squamous Cell Carcinoma of the External Auditory Canal

Stage	Definition
T1	Tumor limited to external auditory canal without erosion of bone or extension into soft tissue
T2	Tumor with limited bone erosion (not full thickness) of the external auditory canal or radiographic evidence of limited (less than 0.5 cm) of soft tissue involvement (includes tumors extending through cartilaginous fissures or bone-cartilaginous junction of the external auditory canal)
T3	Tumor eroding the osseous external auditory canal (full thickness) with limited (less than 0.5 cm) of soft tissue involvement or tumor involving the middle ear or mastoid, or presentation with facial paralysis
T4	Tumor involving the cochlea, dura, medial wall of the middle ear, petrous apex, or surrounding soft tissue

Modified from Arriaga M et al: Staging proposal for external auditory meatus carcinoma based on preoperative clinical examination and computed tomography findings, *Ann Otol Rhinol Laryngol* 99(9 Pt 1):714-721, 1990.

- Stage IV (T1 or T2 or T3N2M0, T4AnyNM0, AnyTAnyNM1) less than 20%
- Using the T system, mortality rates at 2 years reported as follows:
 - T1 and T2: 0%
 - T3: 44%
 - T4: 83%
- Staging system based on T staging (Table 24-5) found 2-year survival rates for primary squamous cell carcinoma of the external auditory canal included:
 - T1: 100%
 - T2: 80%
 - T3: 50% (survival for T3 tumors was 75% with postoperative radiotherapy, compared with 0% with surgery alone)
 - T4: 7%
 - 2-year survival data directly correlated with the staging system and the use of adjuvant radiotherapy increased survival rate in patients with a T3 lesion.

MERKEL CELL CARCINOMA (MCC) (Fig. 24-36)

Definition: Neuroendocrine carcinoma of the skin, primarily arising from Merkel cells, which may be clinically mistaken for a basal cell carcinoma when it occurs on the face of elderly patients.

Synonyms: Trabecular carcinoma of skin; neuroendocrine carcinoma of skin; undifferentiated carcinoma of skin; small cell neuroepithelial tumor of skin; primary small cell carcinoma of skin

Clinical

- No gender predilection; most common in the seventh to eighth decades of life
- Slow-growing tumor with predilection for cutaneous sites of the head and neck (face), extremities (upper and lower), and buttocks:
 - Propensity to occur in the periocular skin area with about 10% of MCC occurring in this area
- Most present as solitary lesions, but multifocal primary tumors may occur synchronously or metachronously.
- Incidence rates increase with sun exposure and after immunosuppression and organ transplantation:
 - MCC may occur in immunosuppression associated with HIV infection, patients with hematologic malignancies (e.g., CLL, other).
- A significant proportion of MCC has been reported to occur in intimate association with malignant epithelial neoplasms, including:
 - Basal cell carcinoma
 - Squamous cell carcinoma
- Genetic mechanisms underlying the development and tumor progression of MCC are poorly understood, sharing pathogenetic mechanisms with other neoplasms of neural crest derivation.
- Etiology:
 - Merkel cell polyomavirus (MCPyV) considered as the etiologic agent of MCC
 - MCPyV is a member of the human polyomavirus (HPyV) family consisting of 10 members including BK virus (BKV), JC virus (JCV), KI virus (KIPyV), WU virus (WUPyV), HPyV6, HPyV7, trichodysplasia spinulosa virus (TSPyV), HPyV9, and MWPyV.
 - In contrast to the other HPyVs, MCPyV to date is unique in its association with a cancer and thus is the first example of a human oncogenic polyomavirus.
 - MCPyV infection is common, and seroprevalence studies indicate that widespread exposure begins early in life.
 - Majority of adults have anti-MCPyV antibodies and there is a growing body of evidence that healthy human skin harbors resident or transient MCPyV, suggesting that MCPyV infection persists throughout life.
 - Mode of transmission, host cells, and latency characteristics of MCPyV remain unclear.
 - Still not clear whether MCPyV is associated with diseases or lesions other than MCC.

Pathology

Gross

- Usually dome-shaped or nodular lesion with a smooth surface and a red to violaceous appearance; vary in size from 0.5 cm to 9 cm

Fig. 24-36. Merkel cell carcinoma.

A, Merkel cell carcinoma characterized by the presence of a dermal-based diffuse cellular proliferation without involvement of the surface epithelium. **B**, Trabecular, cord-like and cell nest growth patterns. **C**, The cellular infiltrate is composed of cells with round nuclei, dispersed (stippled) chromatin pattern, small eosinophilic nucleoli, and scanty, poorly defined, acidophilic cytoplasm; mitotic figures are seen. Immunoreactivity is present for **(D)** cytokeratin (AE1/AE3) and **(E)** CK20 showing a characteristic paranuclear dot-like staining pattern. Lesional cells are also positive for **(F)** synaptophysin and **(G)** Merkel cell polyoma virus (MCPyV), nuclear staining.

Histology

- Characterized by an undifferentiated malignant small cell infiltrate primarily seen in the dermis and subcutaneous tissues and, generally, not involving the epidermis from which the cellular infiltrate is separated by a narrow rim of papillary dermis (Grenz zone):
 - Epidermotropism including intraepidermal growth as single cells or cell clusters forming Pautrier-like microabscesses or rarely with extensive intraepidermal pagetoid spread uncommonly present
 - Intraepithelial involvement may result in ulceration.
- Growth patterns include trabecular, insular, anastomosing cords, and/or diffuse densely packed cellular infiltrate; neural-type rosettes may be identified.
- Most tumors are composed of intermediate sized cells with rather uniform (monomorphic appearing) round nuclei with delicate, dispersed (stippled or dusty) chromatin pattern creating a pale “washed out” appearance with scanty, poorly defined cytoplasm:
 - Small nucleoli may be seen.
 - Nuclear molding may be present but is not prominent.
- Less often the tumor is composed of predominantly diffusely infiltrating small tumor cells.
- Numerous mitotic figures and necrosis (individual cell and confluent foci) can be seen; crush artifact is usually absent.
- Foci of squamous differentiation, horn pearl formation, and pseudoglandular structures may be seen.
- Invasive growth including lymph-vascular space invasion and invasion into connective tissue structures (muscle, fascia, nerves) may be present.
- A sparse to dense associated mixed inflammatory cell infiltrate composed of mature lymphocytes and plasma cells may be seen in the surrounding connective tissue.
- Histochemistry:
 - Argyrophilia may be seen.
- Immunohistochemistry:
 - Keratin (AE1/AE3, CAM 5.2, OSCAR) positive with a punctate (stippled or dotlike pattern) paranuclear staining
 - Cytokeratin 20 (CK20) positive
 - EMA positive
 - Neuroendocrine markers including synaptophysin, chromogranin (less than 50% of cases), CD56, NSE positive
 - Merkel cell polyoma virus (MCPyV) positive (nuclear staining)

- Increased proliferation rate of greater than 90% seen by Ki67 staining.
- Calcitonin and CD117 (c-kit) may be positive.
- S100 protein, melanoma markers (HMB45, melan A, tyrosinase, MART-1, MITF, SOX10), CD45 (leukocyte common antigen), TTF-1, vimentin, desmin, actin, and CD99 typically negative
- Electron microscopy:
 - Neurosecretory granules; perinuclear whorls of intermediate filaments

Differential Diagnosis

- Basal cell carcinoma:
 - Immunohistochemical findings allow for differentiation.
- Hematolymphoid malignancies
 - Immunohistochemical findings allow for differentiation.
- Metastatic small cell neuroendocrine carcinoma (e.g., pulmonary origin):
 - In contrast to Merkel cell carcinoma, small cell carcinomas of pulmonary origin are CK20 negative; staining for other keratins and neuroendocrine cell markers is essentially the same.

Treatment and Prognosis

- Wide local surgical excision is the preferred treatment, with lymph node dissection when palpable nodes are present.
- Radiotherapy may be beneficial in conjunction with surgery.
- Aggressive tumor that has a tendency to recur in approximately one-third of cases.
- Sentinel lymph node positivity is helpful in predicting the risk of recurrence or metastasis in patients with MCC.
- MCC of the head and neck is often associated with nodal metastasis:
 - Regional lymph node metastases commonly occur (approximately 50%).
 - Distant (visceral) metastasis occurs in approximately 15% and most often spreads to lung, liver, bone, and brain:
- 5-year survival rates of 30% to 64% have been reported.
- Overall mortality rate is approximately 11%.

CERUMINAL GLAND ADENOCARCINOMA

(Figs. 24-37 and 24-38)

Definition: Malignant neoplasm of cerumen-secreting modified apocrine glands (ceruminal glands) located in the external auditory canal.

Fig. 24-37. Ceruminal gland adenocarcinoma.

A, Ceruminal gland adenocarcinoma that at low magnification appears infiltrative with glandular, cribriform, and solid growth patterns. **B**, In contrast to ceruminal adenomas, the adenocarcinomas display loss of nuclear polarity, loss of the glandular double cell layer with identification of only the inner or luminal epithelial cell, cellular pleomorphism, anaplasia, and mitoses; the decapitation-type secretion (apical “snouts”) is focally seen but may not be apparent. **C**, In addition to the other features, ceruminal gland adenocarcinomas may demonstrate perineural invasion (*lower left*), as well as invasion of the auricular elastic cartilage (*right*).

Clinical

- More common in men than in women; occurs over a wide age range but is most frequently seen in the fifth to sixth decades of life
- In addition and in contrast to the symptoms of ceruminal gland adenomas, which include a mass in the external auditory canal, hearing difficulty, and otic discharge, ceruminal gland adenocarcinomas are associated with pain as a more characteristic feature.

Pathology

Gross

- Ulcerated, polypoid, or rounded mass ranging in size from 1 to 4 cm in diameter

Histology

- Well-differentiated ceruminal gland adenocarcinomas may appear similar to their benign counterparts and are differentiated only on the basis of invasive growth.
- Features of adenocarcinoma that differ from the adenomas include:
 - Loss of the glandular double cell layer with identification of only the inner or luminal epithelial cell
 - Cells vary in appearance from those with minimal pleomorphism and atypia to cells with pleomorphism, nuclear anaplasia, and mitoses; the decapitation-type secretion (apical “snouts”) may or may not be apparent.
 - Tissue invasion and destruction

Fig. 24-38. Ceruminal gland adenoid cystic carcinoma.

A, Part of a tympanomastoidectomy showing extensive involvement of the external auditory canal by a malignant neoplasm that proved to be an adenoid cystic carcinoma of ceruminal gland origin. **B**, The histology of the resection specimen included a diffusely infiltrative adenocarcinoma of the subcutaneous tissues of the external auditory canal showing classic cribriform growth pattern of adenoid cystic carcinoma. Although not depicted here, the cell types included a predominant myoepithelial (abluminal) cell proliferation with limited but identifiable admixed true glandular (luminal) cells that typify adenoid cystic carcinoma.

- At the other end of the spectrum, poorly differentiated ceruminal adenocarcinomas occur and are recognized on the basis of their localization in the external auditory canal.
- Immunohistochemistry:
 - In cases retaining dual cell population:
 - Luminal cells are CK7 positive.
 - Basal cells are p63, S100 protein, and CK5/6 positive.
- In addition to the more “conventional” type of ceruminal gland adenocarcinomas, other types of ceruminal gland malignant tumors include:

- Adenoid cystic carcinoma (ACC) and mucoepidermoid carcinoma (MEC) of ceruminal gland origin
- These tumors are morphologically identical to their salivary gland counterparts (see Section 6).
- Ceruminal gland ACC and MEC are extremely uncommon and may in fact represent a primary parotid gland tumor presenting in the external auditory canal.

Differential Diagnosis

- Ceruminal gland adenoma
- Given the proximity of the parotid gland to the external auditory canal, the differential diagnosis for ceruminal gland adenoid cystic carcinoma and mucoepidermoid carcinoma includes direct extension of similar tumors of primary parotid origin:
 - Parotid gland adenoid cystic carcinoma and mucoepidermoid carcinoma should be excluded prior to diagnosing such tumors as being of primary ceruminal gland origin.

Treatment and Prognosis

- En bloc surgical resection is the preferred treatment:
 - Middle ear or temporal bone involvement necessitates more radical surgery.
- Supplemental radiotherapy is recommended.
- Recurrence primarily relates to inadequate surgical excision.
- 5-year overall survival of approximately 50%
- Metastases are rare and include regional lymph nodes and the lung.
- For ceruminal gland adenoid cystic carcinoma and mucoepidermoid carcinoma, wide surgical resection is the recommended treatment with or without supplemental radiotherapy.
- Prognosis for ceruminal gland adenoid cystic carcinoma generally is similar to their salivary gland counterparts, including relatively good short-term (i.e., 5-year) survival but poor long-term (i.e., 10- to 20-year) survival:
 - Metastasis from ceruminal gland adenoid cystic carcinoma may include lungs, kidney, liver, and brain.

ATYPICAL FIBROXANTHOMA (AFX) (Fig. 24-39)

Definition: Pleomorphic predominantly dermal mesenchymal tumor found on actinic-damaged cutaneous sites of older age patients.

Synonyms: Undifferentiated pleomorphic sarcoma of skin; superficial (low-grade) malignant fibrous histiocytoma; pseudosarcoma of skin; pseudosarcomatous dermatofibroma

Fig. 24-39. Atypical fibroxanthoma.

A, Atypical fibroxanthoma (AFX) appears as a solitary, delineated nodular or polypoid mass on the external ear. **B**, The lesion is superficial with surface ulceration and limited depth of invasion and appears as unencapsulated but circumscribed. **C**, The neoplasm is characterized by the presence of a diffuse cellular infiltrate composed of strikingly bizarre and pleomorphic cells with spindle-shaped to oval hyperchromatic nuclei often with multiple nuclei, and prominent foamy cytoplasm (xanthomatous cells) and numerous mitoses including atypical forms. **D**, Higher magnification shows the xanthomatous cells with pleomorphic and hyperchromatic nuclei, large eosinophilic nucleoli, prominent foamy cytoplasm, and the presence of atypical mitotic figures.

Clinical

- No gender predilection; elderly patients
- Commonly involving the head and neck including ears, cheeks, and nose
- Prior consideration of a second, less common form affecting younger patients involving superficial sites on the limbs and trunk now considered to be examples of atypical fibrous histiocytoma
- Present as an asymptomatic solitary growth on the affected body site:
 - Bleeding, pruritus, and pain may occur.
- Etiology related to solar and therapeutic radiation supported by:
 - Common occurrence on sun-damaged skin
 - Frequent association with other actinic lesions, including basal cell carcinoma and squamous cell carcinoma
 - Identification of ultraviolet related mutations (p53) and photoproducts
 - Incidence of previous radiation varies from less than 5% to more than 50%.
 - Latent period of approximately 10 years between previous radiation and development of AFX in keeping with radiation-induced tumors.
- May occur in immunosuppressed patients in association with:
 - HIV infection
 - Transplant patients on immunosuppressive agents

Pathology

Gross

- Solitary, firm nodule frequently associated with ulceration and measuring from 1 to 2 cm in diameter

Histology

- Unencapsulated but generally circumscribed neoplasm arising in the dermis and characterized by a bizarre cellular component arranged in a vague fascicular pattern; a storiform growth pattern is infrequently seen.
- Junctional activity between the neoplasm and the overlying epidermis is absent:
 - Grenz zone of uninvolved dermis present
 - Surface atrophy or ulceration may be present.
- Cells are strikingly pleomorphic and bizarre, varying from spindle-shaped, plump, or rounded with hyperchromatic nuclei often with multiple nuclei and large acidophilic nucleoli.
 - Larger cells may have foamy cytoplasm that is reminiscent of lipid-rich histiocytic cells.
 - In some cases, a pleomorphic component may be absent.
- Multiple, atypical, multipolar mitotic figures are present.

- Necrosis is rarely seen.
- Secondary findings may include:
 - Mild chronic inflammatory cell infiltrate
 - Prominent stromal myxoid change
 - Hemorrhage and hemosiderin deposition
 - Osteoclast-like giant cells
 - Osteoid deposition
 - Chondroid material may rarely be present.
- Multinucleated, osteoclastic-like giant cells, as well as osteoid may rarely be present:
 - Osteoclastic-like multinucleated giant cells are intimately associated with atypical, large pleomorphic, and multinucleated cells.
 - Immunostaining of the multinucleated cells shows variable CD68 and actin (HHF35 and smooth muscle actin).
 - Osteoclast-like multinucleated giant cells show variable expression for receptor activator of factor- κ B (RANK), a tumor necrosis factor receptor family member normally expressed in plasma membrane of osteoclasts and their precursors, and indicate greater support that these cells are neoplastic rather than reactive, representing transformation and/or fusion of recruited non-neoplastic histiocytes.
- Superficial areas adjacent to the tumor show solar elastosis and vascular proliferation:
 - Prominent stromal sclerosis may be present.
 - Keloid-type collagen may be present.
- Histochemistry:
 - Intracytoplasmic diastase-resistant, PAS-positive granular material may be seen.
- Immunohistochemistry:
 - Variable staining for CD68 (KP1), muscle-specific actin, smooth muscle actin
 - Strong CD10 reactivity:
 - Lacks specificity
 - CD99, CD163, and CD117 may be present.
 - Absent staining for cytokeratins and S100 protein:
 - Rare cases are cytokeratin positive but typically negative for CK5/6 and p63, although focal p63 (and EMA) staining may be present.
 - Dendritic cells in association with the neoplasm will be S100 protein positive.
 - Negative for desmin and melanoma markers (e.g., HMB-45, Melan-A, tyrosinase, MART-1, MITE, SOX10):
 - Aberrant HMB45 and MART-1 (melanoma antigen recognized by T cells-1) staining reported limited to the large, multinucleated cells with vacuolated cytoplasm.
 - Absence of endothelial markers including CD31, factor VIII-related antigen, CD34, ERG1, Fli1:
 - Histiocytes may be CD31 positive.

- Electron microscopy:
 - Ultrastructural variability with evidence of fibrohistiocytic and myofibroblastic features and to a lesser extent features of Langerhans cells
 - Absence of features indicative of epithelial differentiation (e.g., prominent intercellular bridges, tonofibrils) or melanocytic differentiation (e.g., premelanosome, melanosomes)
- Cytogenetics and molecular biology:
 - Deletions on chromosomes 9p and 13q;
 - Similar to genetic alterations in undifferentiated high-grade pleomorphic sarcoma suggesting common pathogenetic pathway
 - Statistically significant differences of genetic alterations between AFX and undifferentiated high-grade pleomorphic sarcoma concerning deletions on 1q, 3p, 5q, 11p, 11q; gains on 7q and 12q; and high-level gains on 5p and 11q;
 - Genetic differences may contribute to the different biological behavior of these two tumors.
- Unusual variants of AFX include:
 - Clear cell variant characterized by:
 - Sheets of large cells with foamy cytoplasm and hyperchromatic, polyploid nuclei with frequent mitoses, including atypical mitoses
 - Clear cells express CD68 but not CD3, CD20, CD34, S100 protein, muscle-specific actin, factor XIIIa, melan-A, carcinoembryonic antigen, or cytokeratin.
 - Differentiation from balloon cell melanoma, sebaceous carcinoma, pleomorphic liposarcoma, chordoma, parachordoma, tricholemmal carcinoma, and clear cell squamous cell carcinoma predicated on differentiating immunohistochemical staining.
 - Granular cell variant
 - Spindle cell, nonpleomorphic variant:
 - Frequently immunoreactive for SMA and calponin
- Uncommonly, pigmentation may occur:
 - These lesions have been termed pigmented atypical fibroxanthoma.
 - Pigmented atypical fibroxanthoma can be easily mistaken for malignant melanoma clinically and histopathologically.
 - Pigmentation is felt to represent hemorrhage with neoplastic cells ingesting and degrading erythrocytes following intratumoral hemorrhage and to accumulate hemosiderin in their cytoplasm.
 - Pigment stains for iron
- Pseudoangiomatous features and aberrant expression of CD31 and Fli1 may be present, creating potential diagnostic difficulties with cutaneous angiosarcoma:
 - Staining for CD34, ERG is negative.
 - S100, HMB-45, desmin, p63, and cytokeratins negative.

Differential Diagnosis

NOTE: The diagnosis of atypical fibroxanthoma is one of exclusion.

- Spindle cell squamous carcinoma (SCSC):
 - Presence of a differentiated squamous cell component ranging from dysplasia to carcinoma in situ to invasive carcinoma in conjunction with a malignant spindle and/or epithelioid cell component is diagnostic for SCSC.
 - Immunoreactivity for epithelial/squamous cell markers (keratins, p63) differentiates spindle cell squamous carcinoma from AFX.
- Malignant melanoma:
 - Nested growth pattern, junctional changes, and melanin pigment are features of malignant melanoma and not AFX.
 - Presence of S100 protein and melanocytic markers allows for differentiation.
- Dermatofibrosarcoma protuberans (DFSP):
 - Contrasting histologic features should allow for differentiation.
 - DFSPs are CD34 positive.
- Angiosarcoma:
 - Presence of endothelial-related markers (CD31, Factor VIII-related antigen, CD34, ERG, Fli1)
- Leiomyosarcoma:
 - Immunohistochemical stains should allow for separating AFX from leiomyosarcoma, the latter tumor showing reactivity for myogenic markers, including actins (muscle specific and smooth muscle actin) and desmin.
- Undifferentiated pleomorphic sarcoma (UPS):
 - If a tumor has the histologic features of AFX but is large (greater than 2 cm in diameter), extensively involves the subcutis, is deeply infiltrative (penetrates fascia and muscle), shows necrosis or vascular invasion, then it should be considered as a UPS.
 - This distinction is important as therapy for UPS includes surgery with supplemental irradiation.
 - UPS has a propensity for recurrences and metastases and a poor prognosis.

Treatment and Prognosis

- Complete surgical excision is the preferred treatment and is curative.
- Prognosis is excellent.
- Local recurrence is uncommon (7%) and is related to incomplete excision.
- Recurrent tumors may present as a large mass in the deep soft tissue and these neoplasms should be considered and treated as a bona fide UPS.
- AFX may metastasize but these metastasizing AFX may in fact represent (superficial) UPS.

DERMATOFIBROSARCOMA PROTUBERANS (DFSP) (Fig. 24-40)

Definition: Nodular cutaneous fibrohistiocytic tumor of intermediate malignancy characterized by storiform pattern with a tendency for local recurrence but infrequently metastasizes.

Synonyms: Progressive and recurrent dermatofibroma

Clinical

- More common in men than in women; typically present in early or middle adults:
 - May occur in pediatric ages
 - Most frequently occur on the trunk and upper and lower extremities (approximately 85% of cases) but
- approximately 15% occur in cutaneous sites of the head and neck.
 - Clinical presentation is typically that of a slow but persistent growth over extended periods of time (months to years).
 - Clinical appearance of the lesion is usually that of a firm, nodular, or plaque-like cutaneous lesion often with surrounding red to blue discoloration:
 - Less commonly, multiple small subcutaneous nodules are present.
 - Rarely, may appear an area of atrophy (atrophic variant of DFSP)
 - Nodular or plaque-like lesion remains stable for a period of time and then may rapidly develop into one or more nodules, creating the “protuberant” clinical appearance:
 - May reach large sizes especially if neglected

Fig. 24-40. Dermatofibrosarcoma protuberans.

A, Dermatofibrosarcoma protuberans characterized by the presence of a hypercellular subcutaneous proliferation separated from the dermis; unlike the epithelium in dermatofibroma, the overlying epithelium in DFSP usually is not hyperplastic. **B,** Higher magnification shows characteristic storiform growth of relatively uniform-appearing spindle-shaped cells and presence of a rather inconspicuous vascular pattern. **C,** DFSP may show hypocellular and myxoid foci seen here adjacent to a more cellular area. **D,** Diffuse CD34 reactivity.

- No specific link to known etiologic factors, although DFSP has occurred in association with prior trauma, acrodermatitis enteropathica, BCG vaccination site, exposure to arsenic, rapid enlargement during pregnancy, and acanthosis nigricans.

Pathology

Gross

- Solitary, gray-white, circumscribed nodular subcutaneous mass varying in size but with an average size of approximately 5 cm; may achieve extremely large sizes
- Recurrent lesions are often characterized by the presence of multiple discrete nodules.
- Overlying skin may be ulcerated.
- Extension into adjacent structures such as skeletal muscle is uncommon; also, rare tumors may be limited to the subcutis without dermal involvement.
- Degenerative changes, including cyst formation, hemorrhage, and myxoid change may be present but necrosis is rare.

Histology

- Cellular neoplasm diffusely infiltrating the dermis and subcutis:
 - May reach epidermis or not involve the dermis separated by an uninvolved zone of dermis
 - Overlying epidermis typically lacks hyperplastic changes as seen in cutaneous fibrous histiocytomas (dermatofibromas).
 - In its depth the tumor spreads along connective tissue septa or infiltrates adipose tissue in an interdigitating pattern, creating a lace-like appearance.
- Main portion of the tumor shows the presence of a cellular proliferation of slender spindle-shaped cells arranged in a characteristic storiform growth pattern and inconspicuous vascular pattern:
 - Spindle-shaped cells are relatively uniform (monotonous), with little nuclear pleomorphism, low to moderate mitotic activity (fewer than 5 mitoses per 10 high-power fields), and absence of necrosis.
- Multinucleated giant cells and xanthoma cells are uncommon but may be present.
- An associated inflammatory cell infiltrate and myxoid change may be seen:
 - Myxoid areas may be pronounced and when prominent the storiform pattern becomes less distinct with a more prominent vascular pattern resembling features of a myxoid liposarcoma.
- Peripheral portions of the tumor may appear deceptively bland as a result of attenuation of the neoplastic cells at the advancing edge of the tumor;

superficially, the neoplastic cells may or may not reach the epidermis.

- An unusual feature that can rarely be seen is the presence of a nonneoplastic myoid nodule or ball centered around a vascular structure; this finding may represent an unusual vascular response.
- Histology of metastatic foci is similar to that of the primary tumor.
- Immunohistochemical findings include:
 - Consistent CD34 and vimentin positive
 - Muscle-specific actin positive in approximately 80%
 - Factor XIIIa, cytokeratin, S100 protein, HMB45, melan-A, and desmin negative
- Ultrastructure:
 - Elaborate cell processes, desmosomes, and incomplete basal lamina
- Cytogenetics and molecular biology:
 - Supernumerary ring chromosomes consisting of low-level amplification of sequences from chromosomes 17 and 22, and 8 or linear translocation:
 - Ring chromosomes in adult cases
 - Linear translocation derivative in pediatric cases
 - Breakpoints from the rings and translocations fuse exon 2 of the platelet-derived growth factor β -chain (PDGF- β) gene to exons on collagen type 1 α 1 gene (*COL1A1*), resulting in fusion transcript *COL1A1-PDGF- β* consistently identified in DFSP
 - Approximately 8% of DFSP are fusion negative.

Differential Diagnosis

- Benign fibrous histiocytoma (dermatofibroma), which in contrast to DFSP:
 - Commonly occurs on extremities
 - Less distinct storiform growth
 - Presence of plump spindle cells often admixed with inflammatory cells, giant cells, and siderophages
 - Typically CD34 negative
 - Typically lacks subcutaneous extension
- Undifferentiated pleomorphic sarcoma (UPS), which in contrast to DFSP shows:
 - Greater nuclear pleomorphism, mitotic activity, and necrosis
 - Deeper location
 - More rapid growth
- Diffuse neurofibroma, which in contrast to DFSP:
 - Lacks highly cellular areas and increased mitotic activity
 - May show features of neural differentiation (e.g., tactoid structures)
 - Show S100 protein reactivity

- Myxoid liposarcoma, which in contrast to DFSP:
 - Are CD34 negative
 - Include presence of lipoblasts
 - Are typically present in deeper locations

Treatment and Prognosis

- Wide surgical excision is the preferred treatment to include at least 2- to 3-cm margins.
- In the head and neck, approximately 50% to 75% recur as compared with a recurrence rate of 20% to 55% from all other sites:
 - Adequate initial surgical resection essential for minimizing recurrences
 - Risk of recurrence correlates with extent of wide excision:
 - Excision margin of 3 cm or more recurrence rate of 20%
 - Excision margin of 2 cm or less recurrence rate of 41%
 - Recurrences usually develop within 3 years of initial surgery but approximately one-third of patients may develop recurrence after 5 years.
- Mohs surgery advocated in treatment of DFSP:
 - Offers potential to achieve clear margins with minimal excision of normal tissue
 - Local recurrence rates following Mohs reported to be less than 10%
- Imatinib is a potent and specific inhibitor of several protein-tyrosine kinases, including the PDGFRs:
 - Neo-adjuvant use of imatinib in DFSP is efficacious and well tolerated.
 - Imatinib may provide an alternative for the treatment of unresectable or partially resectable tumors, thereby possibly improving the effectiveness of surgery.
- Radiotherapy recommended for:
 - Large, unresectable tumors
 - Postoperatively in margin-positive cases
- Conventional DFSP (in the absence of sarcomatous transformation) infrequently metastasizes:
 - May be a late event in the disease course such that long-term follow-up may reveal increased metastatic rates
 - Approximately 75% of metastases occur via hematogenous spread including to the lungs:
 - Due to low-grade behavior, resection of isolated lung metastases is advocated.
 - Other sites of metastatic spread include brain and bones.
 - Approximately 25% have locoregional lymph node metastasis; as such regional node dissection is generally not indicated.
 - Metastasis usually occurs in the setting of tumor recurrence.
- Sarcoma arising in DFSP:
 - Referred to as fibrosarcomatous variant of DFSP
 - Characterized by the presence of foci of conventional fibrosarcoma within a DFSP
 - Shares clinical features of DFSP
 - Histologically include sarcomatous foci in at least 5% to 10% of the tumor characterized by fascicular growth pattern, high nuclear grade features, increased mitotic activity (more than 7 mitoses per 10 high-power fields), and decreased CD34 immunoreactivity
 - Increased proliferation rate as determined by Ki67 (MIB1) staining
 - Increased p53 immunoreactivity
 - Aggressive biologic behavior as might be suggested by presence of sarcomatous component is debatable:
 - With wide local excision including clear margins, local recurrence rates similar to DFSP with no metastasis

Additional Facts

- Giant cell fibroblastoma is closely related to DFSP and might represent the juvenile form of DFSP based on:
 - Shared clinical and histologic findings with DFSP
 - Presence of CD34 reactivity
 - Rearrangement of chromosomes 17 and 22
- Bednar tumors also referred to as pigmented dermatofibrosarcoma protuberans are:
 - Tumors that resemble DFSP with the additional presence of melanin
 - Uncommon tumors
 - Share clinical, pathologic (gross, microscopic), and genetic features to DFSP
 - Overall behavior considered similar to DFSP
 - May display fibrosarcomatous areas
 - Rare examples of metastatic tumor to the lungs
- Perineurial cell differentiation in DFSP has been suggested based on:
 - Expression of epithelial membrane antigen (EMA)
 - Ultrastructural findings of perineurial cell features, such as thin long bipolar cytoplasmic processes, pinocytotic vesicles, fragments of external lamina and/or external lamina-like material, attachment plaques, and desmosome-like junctions may be present.
 - However, the presence of claudin-1 in perineuromas and absence of claudin-1 in DFSP weigh against perineurial cell differentiation in DFSP.

MALIGNANT NEOPLASMS OF THE MIDDLE EAR (Fig. 24-41)

MIDDLE EAR SQUAMOUS CELL CARCINOMA (ME-SCC)

Definition: Malignant epithelial tumor of epidermoid cells arising as a primary neoplasm from the middle ear mucosal epithelium.

Clinical

- No gender predilection; most commonly seen in the sixth to seventh decades of life
- Majority of patients have a long history of chronic otitis media usually greater than 20 years in duration.
- Development of a middle ear squamous cell carcinoma should be suspected in patients with a long

Fig. 24-41. Middle ear squamous cell carcinoma.

A, Middle ear squamous cell carcinoma showing an infiltrative neoplasm occurring in the background of chronic otitis media, the latter including a chronic inflammatory cell infiltrate, glandular metaplasia (*extreme right*), and tympanosclerosis (*upper left*). **B,** At higher magnification the squamous cell carcinoma is keratinizing and well differentiated.

history of chronic otitis media with the following clinical manifestations:

- Sudden onset of pain out of proportion to the clinical extent of disease
- Onset or increase of otorrhea, which is often hemorrhagic
- Lack of clinical resolution following therapeutic doses of antibiotics
- Early symptoms include pain with radiation to the scalp and face and hearing impairment; late symptoms include facial palsies and vertigo.
- Etiology linked:
 - To radiation treatment for intracranial neoplasms and, although no longer used, radiotherapy for middle ear inflammatory conditions
 - The high-risk human papillomavirus types 16 and 18 identified in middle ear squamous cell carcinomas raises HPV as a possible etiologic factor in the development of middle ear squamous cell carcinoma, although a direct cause and effect has not been established.
- Although concomitant cholesteatomas can be seen in up to 25% of cases, there is no correlation between cholesteatomas and the development of a middle ear squamous cell carcinoma.

Pathology

Histology

- Varies from well to poorly differentiated squamous cell carcinoma with morphologic features identical to squamous cell carcinomas of other sites.
- Carcinoma may or may not be seen arising from the middle ear mucosa.
- Often evidence of chronic otitis media is seen in association with the infiltrating carcinoma as demonstrated by the presence of a chronic inflammatory cell infiltrate, calcifications (tympanosclerosis), and glandular metaplasia.
- Desmoplastic stromal response is often present.
- Evidence of a cholesteatoma may be present.
- Subtypes such as undifferentiated (lymphoepithelial-like) carcinoma of the middle ear identified: (Fig. 24-42)
 - Histologically similar to nasopharyngeal counterpart
 - In situ hybridization for Epstein-Barr encoded RNA (EBER) positive

Differential Diagnosis

- Cholesteatoma
 - Cholesteatoma is characterized by a bland keratinizing squamous epithelium lacking cytomorphic atypia or invasive growth.

Fig. 24-42.

A, Lymphoepithelial-like carcinoma of the middle ear characterized by scattered epithelioid cells with enlarged nuclei surrounded by mixed lymphoplasmacytic cell infiltrate; **B**, the lesional cells are immunoreactive for cytokeratin (CAM5.2) and **(C)** in situ hybridization for Epstein-Barr–encoded RNA (EBER). The patient presented with conductive hearing loss with the identification of a mass wholly confined to the middle ear space without extension from a primary nasopharyngeal neoplasm.

- Metastatic squamous cell carcinoma from a distant site or extension from a squamous carcinoma from an adjacent site (external ear, nasopharynx, parotid gland, or skin):
 - Clinical evaluation to exclude one of these possibilities is indicated prior to rendering a diagnosis of a primary middle ear squamous cell carcinoma.

Treatment and Prognosis

- Radical surgery (i.e., radical mastoidectomy, temporal bone resection) with postoperative radiotherapy is the treatment of choice.
- Combined radical surgery and radiotherapy are the preferred treatment modalities, radical radiotherapy (55 Gy in 20 daily fractions) alone achieves comparable results in terms of local control and cancer-specific survival and is a viable option in the treatment of ME-SCC.
- In advanced disease, chemotherapy may be of benefit.
- Prognosis is poor with 5- and 10-year survival rates of 39% and 21%, respectively.
- Reported 5-year overall survival (OS), disease-specific survival (DSS), and disease-free survival (DFS) of 77%, 79%, and 52%, respectively
- Upfront complete resection (i.e., lateral temporal bone resection), when combined with postoperative radiation therapy, may improve survival and decrease recurrence.
- Neoplasms often present in advanced stages with extensive bone destruction and spread to the eustachian tube, external auditory canal, mastoid, jugular fossa, internal auditory canal, and brain.
- Metastases may occur but are considered uncommon.
- Bony capsule of the labyrinth is resistant to the spread of tumor.

MIDDLE EAR ADENOCARCINOMA (Fig. 24-43)

Definition: Malignant glandular neoplasm arising from the middle ear mucosa.

Clinical

- Rare neoplasm:
 - Metastases to the middle ear from adenocarcinomas of other (distant) sites must be considered.
- No gender predilection; occurs over a wide age range between the second to sixth decades of life.
- Symptoms are typically present for many years and include progressive hearing loss and a unilateral draining ear; pain and vestibular manifestations are uncommon.

Fig. 24-43. Middle ear adenocarcinoma.

A, (left) Middle ear neoplasm that is gland forming and infiltrative that at higher magnification **(right)**, has a complex growth, including a cribriform or back-to-back pattern with cellular pleomorphism. **B,** Another example showing complex growth, including a cribriform or back-to-back pattern with cellular pleomorphism, mitotic figures, and confluent area of tumor necrosis **(lower right)**.

- Otoloscopic examination in the majority of cases will identify an intact tympanic membrane with tumor confined to the middle ear space with possible extension to the mastoid; occasionally, and similar to the middle ear adenoma, the adenocarcinoma will perforate through the tympanic membrane with extension into and presentation as an external auditory canal mass.
- Etiology is unknown:
 - No association between chronic otitis media and the development of middle ear adenocarcinoma

Pathology

Gross

- Variation in appearance from gray-white to red-brown, rubbery to firm mass to spongy and cystic appearing

- May attain large sizes filling the middle ear space and encasing the ossicles

Histology

- Unencapsulated lesion with diffuse proliferation of glands showing complex gland-in-gland (cribriform) growth composed of cells with marked nuclear pleomorphism and increased mitotic activity:
 - Mucocytes are not identified.
- Extensive infiltration of surrounding soft tissue structures including perineural and perivascular invasion and invasion of bone is usually identified.
- Papillary and cystic variant (papillary cystadenocarcinoma) lined by cells with hyperchromatic nuclei and vacuolated cytoplasm containing luminal eosinophilic secretions with scalloped edges can be identified.
- Histochemistry:
 - Intraluminal but not intracytoplasmic mucin positive material may be seen.
- Immunohistochemistry:
 - Cytokeratin and epithelial membrane antigen are consistently positive.
 - Immunoreactivity absent for neuroendocrine markers, organ specific markers and/or markers reactive in other adenocarcinomas:
 - Thyroid: thyroglobulin, TTF-1, PAX8
 - Prostate: prostate specific antigen (PSA), prostatic acid phosphatase (PAP), prostein
 - Kidney: renal cell carcinoma antibody, CD10, PAX2, PAX8, CAIX
 - Breast: mammaglobin, BRST-2, GATA3
 - Lung: Naspin A, TTF1
 - Colorectal: CDX2, CK20, villin

Differential Diagnosis

- Middle ear adenoma.
- Confinement to the middle ear space and association with the middle ear mucosa are supportive evidence of origin from the middle ear; nevertheless, metastatic adenocarcinoma from a separate site must be excluded prior to treatment:
 - Metastases to the middle ear and temporal bone can be seen from all sites but are most common from breast, lung, kidney, gastrointestinal tract, larynx, skin (melanoma), and prostate gland.

Treatment and Prognosis

- Complete surgical excision is the preferred treatment.
- In general, these are slow-growing neoplasms that are locally aggressive but do not metastasize.
- Papillary cystadenocarcinomas are considered low-grade malignant tumors.
- Death may occur as a result of direct intracranial extension.

RHABDOMYOSARCOMA (RMS)

Definition: Malignant neoplasm showing skeletal muscle differentiation.

Clinical

- In the head and neck, RMS is primarily but not exclusively a disease of the pediatric population
- In the head and neck, parameningeal tumors are the most common:
 - Most frequent sites in the head in neck include nasopharynx > middle ear and mastoid > sinonasal tract > soft tissues of the neck > oral cavity (tongue, lip, palate).

- For more complete discussion including images, see Section 3, The Pharynx.

ENDOLYMPHATIC SAC PAPILLARY TUMOR (ELSPT)

(Figs. 24-44 through 24-46)

Definition: Uncommon but distinct neoplasm of probable endolymphatic sac epithelial origin possibly representing a manifestation of von Hippel-Lindau (VHL) syndrome.

Synonyms: Adenoma of endolymphatic sac, adenoma of temporal bone or mastoid, adenocarcinoma of

Fig. 24-44. Endolymphatic sac papillary tumor.

A and **B**, Pre- and post-contrast-enhanced T1-weighted images. **C**, T2-weighted image. The tumor has focal heterogeneous signal intensity on both T1-weighted and T2-weighted images caused by blood products and calcification. It shows heterogeneous enhancement after contrast administration. **D**, CT image in bone algorithm shows a destructive lesion with irregular, moth-eaten bone margins extending to the medial mastoid. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 20-179, p 1372.)

Fig. 24-45. Endolymphatic sac papillary tumor.

A, Endolymphatic sac papillary tumor characterized by a papillary growth pattern. **B**, The epithelial component is distinct, composed of a single layer of cuboidal to columnar-appearing cells with delineated cell borders. **C**, In this example, despite the papillary architecture, the epithelial component is not as readily identifiable. **D**, Even at higher magnification, the epithelium is indistinct and the overall process may be mistaken for granulation tissue. The epithelial component is diffusely immunoreactive for cytokeratins, including **(E)** CAM5.2 and **(F)** CK7.

temporal bone or mastoid, low-grade adenocarcinoma of probable endolymphatic sac origin, papillary adenoma of temporal bone, aggressive papillary tumor of temporal bone, aggressive papillary middle ear tumor, and Heffner tumor

NOTE: Owing to its aggressive behavior this neoplasm was initially considered to be low-grade adenocarcinoma. Although the majority of ELSPTs have an indolent biologic course, raising the possibility that these neoplasms may be benign or at worst of

Fig. 24-46. Endolymphatic sac papillary tumor.

A, This inner ear tumor localized to the petrous apex shows the appearance of a thyroid lesion, including variably sized cystic spaces containing eosinophilic (colloid-like) material. **B**, At higher magnification, the presence of a papillary architecture, colloid-like material, and variability in the nuclear size and shape with dispersed to clear-appearing nuclear chromatin and an occasional intranuclear inclusion mimics the histology of a papillary thyroid carcinoma. Thyroglobulin and thyroid transcription factor 1 (TTF-1) staining were negative (not shown).

indeterminant malignant potential, the documented reports of metastatic ELSPT would support its classification as an adenocarcinoma.

Clinical

- No gender predilection; occurs over a wide age range from the second through eighth decades of life
- Most common symptom is unilateral hearing loss ranging from 6 months to 18 years in duration:
 - Hearing loss is most frequently sensorineural rather than conductive, but mixed types of hearing loss also occur.
- Other symptoms include tinnitus, vertigo, ataxia, and cranial nerve deficits.

- CT scan and MRI:
 - Lytic temporal bone lesion measuring from 4 to 6 cm
 - Center of the lesions most often seen at or near the posterior-medial face of the petrous bone.
 - Extension of tumor to the posterior cranial cavity leads to suggestions that the tumor originated from the cerebello-pontine angle; extension results in cerebellar involvement and evidence of compression and/or shifting of the fourth ventricle, brainstem, or pineal gland.
 - Angiographic studies show a vascular or hyper-vascular lesion.
- Endolymphatic sac origin for these tumors supported by:
 - Early clinical manifestations of vestibular disease, including sensorineural hearing loss, tinnitus, and episodic vertigo
 - Radiographic features showing the tumor to grow in the region of the posterior-medial petrous ridge, a site where the endolymphatic sac is located
 - Intraoperative identification of an *in situ* tumor (originating from within the endolymphatic sac)
 - Morphologic similarities and shared immunohistochemical and ultrastructural features of the tumor with the normal endolymphatic sac epithelium
 - Histologic studies of the epithelium of normal human mature endolymphatic ducts and sacs in archival temporal bone sections showed hyperplastic tubular outgrowths, usually situated in the intraosseous portion of the endolymphatic sac:
 - Such appearances imply that the epithelium of the endolymphatic ducts and sacs has the potential of producing a malignant papillary glandular neoplasm.
- Diagnosis is based on clinical, radiographic, and pathologic correlation.
- Diagnosis of ELSPT should prompt the clinician to exclude the possibility that the patient has von Hippel-Lindau (VHL) syndrome:
 - VHL germline mutation with an autosomal-dominant inheritance pattern usually identified
 - Tumor suppressor gene for VHL has been identified at chromosome 3p25-p26
 - Patients with VHL have a predisposition to the development of numerous CNS and abdominal organ tumors (Box 24-3).
 - Approximately 1 in 35,000 to 40,000 people have VHL, of whom 10% to 15% have ELSPT.

Pathology

Histology

- Histopathologic appearance of ELSPT is variable.
- Most show papillary and focally cystic growth:

BOX 24-3 Neoplasms Associated with von Hippel-Lindau Syndrome

- Retinal angiomas
 - Cerebellar and spinal hemangioblastomas
 - Endolymphatic sac papillary tumor
 - Renal cysts and cystadenomas
 - Pancreas: microcystic adenoma; endocrine tumors
 - Pheochromocytoma
 - Epididymal cyst and cystadenoma
- Papillary structures are generally not complex in their growth.
 - Neoplastic cells vary in appearance from flattened or attenuated appearing cells to columnar appearing cells and are most often only a single row of cells.
 - Occasionally, surface epithelial cells may have the appearance suggesting a double layer of cells (epithelial and myoepithelial); however, the “outer” row of cells, in all probability, represent a stromal element as they have not been shown to be immunoreactive with epithelial markers.
 - Epithelial cells have uniform nuclei that are usually situated either in the center of the cells or toward the luminal aspect and have a pale eosinophilic to clear appearing cytoplasm; the latter may predominate in any given tumor.
 - Cell borders may be seen but, not infrequently, the neoplastic cells lack a distinct cell membrane.
 - Due to the absence of a distinct cell membrane around the neoplastic cells, a sharp demarcation separating the neoplastic cells from the subjacent granulation tissue is not present.
 - This appearance may create diagnostic confusion so that the neoplastic proliferation is not appreciated, and the entire process may be viewed erroneously as reactive.
 - This interpretation is further enhanced by the presence in the stroma of a mixed inflammatory cell infiltrate, fibrosis, vascular proliferation, fresh hemorrhage and/or hemosiderin (within the neoplastic cells or within macrophages), cholesterol granulomas and dystrophic calcification; the latter does not include laminated calcific concretions (psammoma bodies)
 - In some cases, there are hypercellular areas with crowded, variably sized cystic glandular spaces that contain eosinophilic (colloid-like) material remarkably similar to thyroid tissue.
 - In all cases, pleomorphism is minimal, and mitotic activity and necrosis are rarely present.
 - A granulation tissue reaction is seen in association with the neoplastic cells and includes small vascular spaces lying in close proximity to the surface epithelium and/or within the stroma of the papillary fronds.

- Histochemistry:
 - Intracytoplasmic diastase-sensitive, periodic acid-Schiff (PAS)–positive material can be seen.
 - Colloid-like luminal material stains strongly with periodic acid Schiff (PAS) with and without diastase digestion.
 - Intracytoplasmic and intraluminal mucin staining is rarely positive.
 - Iron stains are positive.
- Immunohistochemistry:
 - Diffusely cytokeratin positive (AE1/AE3, CAM5.2, CK7)
 - Variable reactivity with epithelial membrane antigen (EMA), S-100 protein, vimentin, neuron specific enolase (NSE), glial fibrillary acidic protein (GFAP), Ber-EP4, synaptophysin, and Leu-7
 - Thyroglobulin, thyroid transcription factor 1 (TTF1), PAX8 negative
- Electron microscopy:
 - ELSPT shows the presence of intercellular junctional complexes, microvilli, basement membrane material, rough endoplasmic reticulum, and intracytoplasmic glycogen and secretory granules.
- Cytogenetics and molecular biology:
 - Germline mutations of the *VHL* tumor suppressor gene are usually detected in patients with ELSPT; however, sporadic cases unrelated to *VHL* occur.

Differential Diagnosis

- Nonneoplastic reactive or inflammatory processes
- Choroid plexus papilloma (CPP):
 - CPPs are intracranial (i.e., intraventricular) tumors
 - Histologic features of CPPs are different from those of ELSPT:
 - CPPs have a complex papillary pattern in which the neoplastic cells are arranged in an orderly layer of columnar epithelial cells situated on delicate fibrovascular stalks.
 - Neoplastic cells of CPPs have a distinct, well-formed continuous basement membrane separating them from the surrounding stromal tissue.
 - Prominent stromal calcification (psammomatoid bodies) and xanthomatous change may be present in CPPs.
 - Immunohistochemical stains assist in differentiating ELSPT from CPP:
 - Cytokeratin positive (similar to ELSPT)
 - Consistent S100 protein and vimentin
 - Focally glial fibrillary acidic protein positive

- Middle ear adenoma:
 - Clinical, radiographic, and pathologic features that are unique to ELSPT should allow for its distinction from middle ear adenoma.
 - Same would apply for the other common neoplasms of the middle ear and temporal bone
- Ceruminous gland adenocarcinoma
- Metastatic adenocarcinoma, particularly papillary carcinoma of the thyroid and renal cell carcinoma:
 - The absence of thyroglobulin, TTF1, and PAX8 reactivity would differentiate ELSPT from metastatic papillary thyroid carcinoma.
 - Metastatic renal cell carcinoma shows immunoreactivity for renal cell carcinoma antibody CD10, PAX2, PAX8, and CAIX, which are not found in ELSPT.
- These tumors are primarily of mesenchymal origin, including matrix-forming such as osteosarcoma and chondrosarcoma.
- Osteosarcomas of the skull:
 - Are uncommon, with approximately 1% to 2% of all osteosarcomas occurring in this location
 - Often arise in the setting of Paget disease of bone, fibrous dysplasia, or secondary to radiotherapy
 - Osteosarcomas of the skull are aggressive tumors with a tendency to metastasize to the lungs and brain and with 5-year survivals of less than 15%.
- Chondrosarcomas of the temporal bone are:
 - Rare
 - Petrous apex and posteromedial aspect of the temporal bone are perhaps the most common sites of occurrence.
 - Are not necessarily lethal tumors as with reported 76% disease-free survival over periods ranging up to 8 years

Treatment and Prognosis

- Radical surgery including mastoidectomy and temporal bone resection that may necessitate sacrifice of cranial nerves is the preferred treatment and is potentially curative.
- Local recurrence will result following inadequate surgical removal; operative morbidity may be high.
- Despite being low grade and slowly growing, these neoplasms are capable of widespread infiltration and destruction and may be lethal.
- Rarely may metastasize
- Prognosis is dependent on the extent of disease and the adequacy of resection:
 - Earlier detection when the tumors are relatively small and confined may decrease the operative-associated morbidity and be curative.
- In 25% of the cases reported, prior temporal bone resection was performed indicative of the initial occurrence of this neoplasm.
- Proposed grading system for ELSPT includes:
 - Grade I: confined to the temporal bone, middle ear, and external auditory meatus
 - Grade II: extends into the posterior fossa:
 - More than half of all ELSPTs are grade II at presentation
 - Grade III: involves the posterior and middle cranial fossae
 - Grade IV: extends to the clivus or sphenoid wing:
 - Very rare and occurs in only 2% to 4% of patients with ESPT

OTHER MALIGNANT TUMORS OF THE MIDDLE EAR AND TEMPORAL BONE

- Although uncommon, a number of other malignant tumors can originate in the middle ear or temporal bone.

- Other malignancies of the middle ear and temporal bones include hematolymphoid, including malignant lymphomas (non-Hodgkin and Hodgkin), leukemia, and plasma cell dyscrasias; middle ear and temporal bone involvement by a malignant hematolymphoid neoplasm often is secondary to primary disease elsewhere.

METASTATIC TUMORS TO THE MIDDLE EAR AND TEMPORAL BONE (SECONDARY TUMORS)

(Fig. 24-47)

- Metastatic tumors secondarily involving the middle ear and temporal bone originate from virtually every site.
- More common malignant tumors to metastasize to this region originate from the breast, head and neck, lungs, and prostate gland.
- Other tumors that may metastasize to this region include malignant melanoma, thyroid carcinomas, and renal cell carcinoma.
- Immunohistochemical staining is often required to confirm the diagnosis of a metastasis to the ear and temporal bone:
 - Breast: Mammaglobin, BRST-2, GATA3 positive
 - Lung: Napsin A, TTF-1, CK7 positive
 - Prostate: PSA, PAP, prostatein positive
 - Melanoma: S100 protein, HMB45, melan A, tyrosinase, MITF1, SOX10 positive
 - Thyroid: Thyroglobulin, TTF1, PAX8 positive
 - Kidney: CD10, RCC, PAX2, PAX8, CAIX positive
- Although metastases to the temporal bone often occur late in the disease course, metastatic

Fig. 24-47. Metastatic tumors to the ear/temporal bone.

A, Metastatic renal cell carcinoma to the temporal bone showing characteristic cells with clear cytoplasm, distinct cell borders, intraluminal red blood cells, and fibrovascular stroma separating neoplastic nests; the lesional cells were reactive for RCC, CD10, PAX2, PAX8, and CAIX (not shown). **B**, Metastatic prostate adenocarcinoma with gland formation and neoplastic cells showing prominent nucleoli and associated inflammatory cell infiltrate and individual cell necrosis. The overall histology is unusual for any primary middle ear or temporal bone malignant tumor prompting consideration for a metastasis. **C**, Immunohistochemical stains show reactivity for prostate specific antigen (*left*) and prostatic acid phosphatase (*right*), confirming the diagnosis of metastatic prostatic adenocarcinoma. In both cases, there was no known history of a primary renal carcinoma and prostate carcinoma and only following the presence and identification of these metastases was a primary cancer of the kidney and prostate gland discovered.

involvement of the temporal bone may represent the initial presentation of a distant malignant disease.

- Metastatic disease to the temporal bone occurs via hematogenous spread but may also occur by direct extension from a nearby primary tumor (e.g., squamous cell carcinoma), meningeal carcinomatosis or

leptomeningeal extension from an intracranial primary neoplasm.

Immunohistochemistry of Middle Ear Neoplasms (Table 25-1)

TABLE 25-1 Immunohistochemical Reactivity of Middle Ear Neoplasms

	CK	EMA	p63	CG	SYN	S100	NSE	GFAP	VIM	DES	Myog
MEA	+	+	–	–	–	–	–	–	–	–	–
MEA/NE	+	+	–	+	+	V	+	–	–	–	–
JTP	–	–	–	+	+	++ [‡]	+	–	–	–	–
MEN	± [*]	+	–	–	–	–	–	–	+	–	–
AN	–	–	–	–	–	+ (N/C)	+	–	–	–	–
ESPT	++ [†]	+		v	v	v	v	v	–	–	–
RMS	– [§]	–	– [¶]	–	–	–	–	–	+	+	+ (N)

AN, Acoustic neuroma; CG, chromogranin; CK, cytokeratin; DES, desmin; EMA, epithelial membrane antigen; ESPT, endolymphatic sac papillary tumor; GFAP, glial fibrillary acidic protein; JTP, jugulotympanic paraganglioma; MEA, middle ear adenoma; MEN, meningioma; Myog, myogenin; (N), nuclear staining; (N/C), nuclear and cytoplasmic; NE, neuroendocrine features; NSE, neuron-specific enolase; RMS, rhabdomyosarcoma; SYN, synaptophysin; VIM, vimentin.

+, Positive; –, negative; +/-, variably positive.

*Cytokeratins can be positive (as a whole may be positive in 20% of cases; may approach 40% positivity in epithelial variants).

[†]AE1/AE3, CAM5.2, CK7.

[‡]Positive in the peripherally situated sustentacular cells; SOX10 (nuclear) reactivity may be present, as well.

[§]May be positive in up to 50% of alveolar rhabdomyosarcomas.

[¶]May be focally positive.

Non-Neoplastic Diseases of the Thyroid Gland

CLASSIFICATION OF NON-NEOPLASTIC LESIONS OF THE THYROID GLAND

See [Box 27-1](#).

BOX 27-1 Classification of Non-Neoplastic Lesions of the Thyroid Gland

Developmental

- Heterotopia/ectopia of thyroid tissues
- Lingual thyroid
- Thyroglossal duct cyst
- Lateral aberrant thyroid, parasitic nodule, and mechanical implantation
- Mediastinal thyroid and other sites of thyroid tissue
- Intranodal thyroid inclusions
- Struma ovarii and associated lesions
- Follicular epithelial metaplasia: squamous; oncocytic
- Others

“Inclusions” in the Thyroid Gland

- Intrathyroidal parathyroid tissue, thymic tissue, salivary gland tissue
- Intrathyroidal epithelial (branchial cleft-like) cysts
- Ultimobranchial apparatus rests
- Intrathyroidal fat, muscle, and cartilage
- Pigment and crystals in the thyroid
 - Iron; lipofuscin; crystals
 - Black thyroid (minocycline)

Nonautoimmune Thyroiditides (Inflammatory, Infectious, and Noninfectious)

- Acute inflammatory conditions
- Infectious thyroiditis
- Granulomatous thyroiditis (subacute thyroiditis; de Quervain)
- Multifocal granulomatous thyroiditis (palpation thyroiditis)
- Invasive fibrous thyroiditis (Reidel disease)
- Radiation thyroiditis
- Drug-induced thyroiditis
- Infectious granulomatous thyroiditis
- Sarcoidosis of the thyroid gland

Autoimmune Thyroiditis

- Chronic (focal) lymphocytic thyroiditis
- Chronic lymphocytic (Hashimoto) thyroiditis
- Others
- Autoimmune hyperthyroidism (diffuse hyperplasia or Graves disease)

Goiters

- Nodular goiter
- Congenital inborn disorders (dyshormonogenetic goiter)
- Amyloid goiter

DEVELOPMENTAL ANOMALIES

Heterotopia or Ectopic Thyroid Tissue ([Figs. 27-1 through 27-3](#))

Definitions: Heterotopia is the presence of otherwise normal-appearing tissue in an abnormal location. Ectopic thyroid tissue is the presence of thyroid in any location other than its normal anatomic position.

Synonyms: Aberrant thyroid rests; choristoma

- Normal thyroid tissue can be found within the soft tissue structures (fat and muscle) of cervical neck:
 - Reflects developmental abnormality and should not be mistaken for malignancy:
 - Thyroid tissue in skeletal muscle often located at or around the isthmus portion of the gland
 - Absence of tissue response such as fibrosis (desmoplasia) and/or the presence of architectural or cytomorphic changes indicative of a neoplasm (i.e., papillary carcinoma) are of assistance in differentiating normal (ectopic) thyroid tissue from neoplastic thyroid tissue.
 - Presence of thyroid tissue within lymph nodes especially located lateral to the jugular vein and carotid artery represents metastatic (papillary) carcinoma; exception would be thyroid tissue in a midline lymph node that may represent thyroid inclusions, but strict criteria must be applied to accept such thyroid tissue as inclusions and not metastatic tumor (see below).

Clinical

- Heterotopic thyroid tissue may be seen in any location from the tongue (foramen cecum at the base of the tongue) to the suprasternal notch (site of the normal gland):
 - May represent failure of descent from foramen cecum (median anlage) or, less likely, differentiation of thyroid tissue in abnormal locations
- Excluding thyroglossal duct cysts, presence of heterotopic thyroid tissue is rare and almost exclusively seen in suprahyoid locations usually located in or close to midline:
 - Most common heterotopic focus for thyroid tissue is base of tongue, referred to as lingual thyroid (see below)

Fig. 27-1. Thyroid tissue in skeletal muscle.

Thyroid follicles can be found within the soft tissue structures of cervical neck, including skeletal muscle and fat, reflecting a developmental abnormality, and should not be mistaken for malignancy. Thyroid tissue in skeletal muscle is often located at or around the isthmus of the gland. The absence of tissue response such as fibrosis (desmoplasia) and/or the presence of architectural or cytomorphic changes indicative of a neoplasm (i.e., papillary thyroid carcinoma) assist in differentiating normal (ectopic) thyroid tissue from neoplastic thyroid tissue.

- Other sites include (cranial to caudal direction):
 - Sella turcica
 - Submandibular region
 - Larynx
 - Trachea
 - Mediastinum (superior > posterior)
 - Aortic arch, pericardium, and heart
 - Esophagus
- More distant sites of heterotopic thyroid tissue include:
 - Duodenal wall
 - Hepatobiliary (liver, porta hepatis, gallbladder, common bile duct)

Fig. 27-2. Thyroid tissue in fat.

Similar to thyroid tissue in skeletal muscle (see previous image) thyroid follicles can be found within the cervical neck fat often located at or around the isthmus of the gland. The absence of desmoplasia and/or the presence of features that may be diagnostic for papillary thyroid carcinoma assist in differentiating normal (ectopic) thyroid tissue from neoplastic thyroid tissue.

- Pancreas
- Adrenal gland
- Retroperitoneum
- Vagina and inguinal region
- Ovarian thyroid tissue is referred to as struma ovarii (see below).
- Rarely, multiple ectopic thyroid tissue may be present in separate sites in same patient.
- Diseases that affect thyroid gland proper may also affect ectopic thyroid tissues, including:
 - Inflammatory diseases (e.g., Hashimoto thyroiditis, Graves disease, others)
 - Goiter
 - Neoplasms

Fig. 27-3. Thyroid ectopia.

Ectopic thyroid tissue in the pancreas.

- Imaging with ^{123}I may establish the diagnosis noninvasively.
- Etiology:
 - None known
 - Rarely, familial thyroid heterotopia may occur.

Pathology

- Histologically, heterotopic thyroid tissue includes presence of normal-appearing, colloid-filled thyroid follicles:
 - Cytomorphologic findings include round to oval nuclei with coarse nuclear chromatin lacking constellation of nuclear features diagnostic for thyroid papillary carcinoma.
 - C-cells are absent.
- Immunohistochemistry:
 - Unnecessary for identification but cells will be:
 - Reactive for thyroglobulin, thyroid transcription factor 1, PAX8, CD56
 - Nonreactive for calcitonin, neuroendocrine markers (e.g., synaptophysin, chromogranin)
- Cytogenetics and molecular genetics:
 - Few reports evaluating molecular alterations in thyroid ectopia were without molecular alterations associated with malignant tumors of follicular cell derivation (*BRAFV600E*, *N-RAS*, *H-RAS*, *K-RAS*).

Differential Diagnosis

- Any thyroid tissue found lateral to large neck vessels (i.e., carotid artery, jugular vein) should be considered metastatic tumor rather than ectopia:
 - Especially true for foci of thyroid follicles in lymph nodes:
 - Represent metastatic papillary thyroid carcinoma even in absence of diagnostic nuclear features

- Different types of malignant neoplasms may be seen uncommonly associated with heterotopic tissues, including papillary carcinoma and follicular carcinoma:
 - In such circumstances, evaluation indicated to exclude origin from thyroid gland proper
 - In presence of malignant follicular-derived neoplasm within thyroid gland proper, presence of thyroid carcinoma in “ectopic” site represents metastatic disease.
 - Only in absence of malignant follicular-derived neoplasm within thyroid gland proper can presence of thyroid carcinoma in “ectopic” site be considered as originating from the ectopic site.
- Presence of thyroid follicles in midline or paramidline lymph nodes may represent thyroid inclusions or metastatic papillary carcinoma (see [Thyroid Tissue in Lymph Nodes](#) later in this chapter).

Treatment and Prognosis

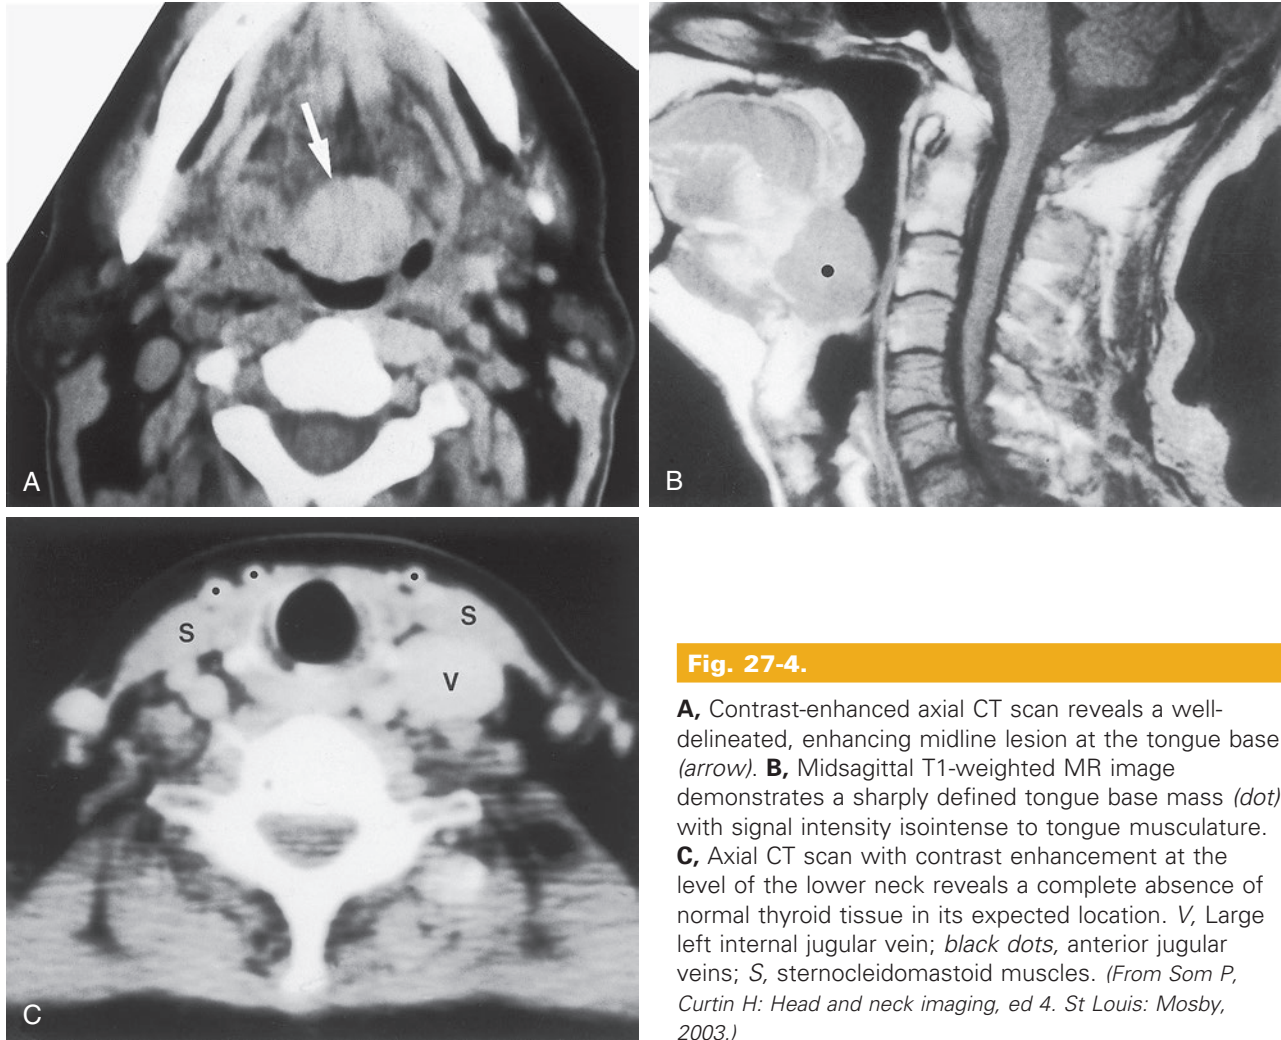

- In general, heterotopic thyroid tissue is benign.
- Complete or partial agenesis of thyroid gland is extremely rare.

Lingual Thyroid (Figs. 27-4 and 27-5)

Definition: Developmental anomaly in which there is abnormal descent of thyroid gland with localization to base of tongue.

Clinical

- Thyroid tissue restricted to lingual region is rare, occurring in 1 in 100,000 persons.
- Affects women more than men (3:1 to 7:1); most often diagnosed in adolescence but may occur over a wide age range from birth to the seventh decade of life
- Most frequently seen along the midline of base of the tongue between the foramen cecum and the epiglottis; rarely, body of the tongue (sublingual) may be affected.
- Majority of patients who are symptomatic are women; contributing factors are thought to be related to puberty, pregnancy, and menopause.
- Most common symptom is dysphagia.
 - Lingual thyroid may grow large, resulting in dyspnea, orthopnea, and severe respiratory distress.
 - Other symptoms may include bleeding, voice changes, a foreign body sensation, snoring, and sleep apnea.
- Clinical presentation:
 - 70% of patients with symptomatic lingual thyroid are hypothyroid.

**Fig. 27-4.**

A, Contrast-enhanced axial CT scan reveals a well-delineated, enhancing midline lesion at the tongue base (*arrow*). **B**, Midsagittal T1-weighted MR image demonstrates a sharply defined tongue base mass (*dot*) with signal intensity isointense to tongue musculature. **C**, Axial CT scan with contrast enhancement at the level of the lower neck reveals a complete absence of normal thyroid tissue in its expected location. V, Large left internal jugular vein; *black dots*, anterior jugular veins; S, sternocleidomastoid muscles. (From Som P, Curtin H: *Head and neck imaging*, ed 4. St Louis: Mosby, 2003.)

**Fig. 27-5. Lingual thyroid.**

Left, The lingual squamous epithelium overlies a submucosa that focally retains its seromucous glands but is predominantly replaced by unencapsulated benign thyroid tissue. *Right*, The thyroid follicular epithelium is essentially normal in appearance.

- 10% suffer from cretinism.
- Hyperthyroidism exceptionally rare finding
- In greater than 75% of patients, cervical thyroid tissue is absent (total migration failure) and lingual thyroid represents only thyroid tissue present:
 - In such situations surgical removal of lingual thyroid results in hypothyroidism.
- Appropriate preoperative clinical work-up for lingual thyroid includes:
 - Routine blood work, including thyroid function tests thyrotropin, thyroxine, and thyroid hormone binding ratio
 - Scintigraphy with technetium or radioiodine studies, computerized tomography, or magnetic resonance imaging to:
 - Determine whether normally placed thyroid tissue is present or absent
 - Determine whether there are other ectopic foci of thyroid tissue (thyroid follicles may be found in hyoid region)

- Determine functional activity of lingual thyroid tissue
- Incisional biopsies must be performed with caution because this may cause sloughing of gland, infection, necrosis, or hemorrhage.
- Radiology:
 - Tc-99m pertechnetate scanning is an efficient diagnostic tool that yields high-quality images in this clinical setting.
 - Computed tomography shows a mass at the base of the tongue with a greater density than the tongue.
 - On MR imaging, a well-defined mass of low-intermediate T2 signal in the midline base of the tongue, neither with invasive tendency nor with a cervical thyroid gland in the normal site, strongly indicates a lingual thyroid.

Pathology

Gross

- Submucosal varying in appearance from smooth to lobulated to nodular mass, with a red color, soft to firm consistency, and ranging in size from 2 to 3 cm:
 - Overlying mucosa may be intact or ulcerated.

Histology

- Thyroid tissue is:
 - Submucosal and unencapsulated
 - May be nodular and hypercellular
 - Thyroid follicular epithelium is essentially normal in appearance (i.e., without evidence of papillary carcinoma).
 - May extend into skeletal muscle
- Immunohistochemistry:
 - Unnecessary for identification but cells will be:
 - Reactive for thyroglobulin, thyroid transcription factor 1, PAX8, CD56
 - Nonreactive for calcitonin, neuroendocrine markers (e.g., synaptophysin, chromogranin)

Differential Diagnosis

- Lymphoepithelial cyst of oral cavity
- Cribiform adenocarcinoma of minor salivary glands of oral cavity (See Section 7):
 - May show histologic similarities to papillary thyroid carcinoma
 - Absence of immunoreactivity for thyroglobulin and TTF-1
- Low-grade nasopharyngeal papillary adenocarcinoma (See Section 3):
 - May show histologic similarities to papillary thyroid carcinoma
 - Lesional cells are:
 - TTF-1 positive (nuclear staining)
 - Thyroglobulin negative

Treatment and Prognosis

- Therapy varies:
 - Asymptomatic euthyroid patients with ectopic thyroid do not usually require therapy but are kept under observation.
 - For symptomatic patients, surgical excision (intraorally or pharyngotomy) is preferred treatment:
 - Transoral robotic surgery (TORS) has provided minimally invasive approach to completely and safely excise ectopic lingual thyroid.
 - In patients without normally situated cervical thyroid tissue or other ectopic foci of thyroid tissue, auto-transplantation of thyroid tissue into the neck muscles can be done.
 - Other modes of therapy include:
 - Shrinking the mass by using thyroid hormones or use radioactive iodine (^{131}I) to ablate the lingual thyroid
 - Use of radioactive iodine results in destruction of other thyroid tissue and may also cause sloughing of the gland and hemorrhage.
 - In case of absence of orthotopic thyroid tissue, long-term thyroid hormone replacement recommended
- Prognosis is good:
 - Surgical resection of lingual thyroid glands achieves significant improvement in patient symptoms with low rates of recurrence.
 - Complications of surgery are uncommon and may include:
 - Postoperative bleeding and epiglottic perforation, airway obstruction secondary to angioedema
- Malignant neoplasms may arise from lingual thyroid:
 - Papillary thyroid carcinoma is the most common type.
 - May be associated with cervical nodal metastasis
 - Treatment best managed with surgical excision of all thyroid tissue followed by radioactive iodine ablation
 - In such circumstances, evaluation indicated to exclude origin from thyroid gland proper
 - In presence of malignant follicular-derived neoplasm within thyroid gland proper, presence of thyroid carcinoma in “ectopic” site represents metastatic disease.
 - Only in absence of malignant follicular-derived neoplasm within thyroid gland proper can presence of thyroid carcinoma in “ectopic” site be considered as originating from the ectopic site.

Thyroglossal Duct Cyst (TDC)

(Figs. 27-6 through 27-11)

Definition: Persistence and cystic dilatation of thyroglossal duct in midline of the neck.

Clinical

- No gender predilection; occurs over a wide age range but the majority of patients present before the fourth decade of life
- Majority of cases occur in the midline of the neck above the thyroid isthmus but below level of the hyoid bone:

Fig. 27-6. Thyroglossal duct cyst.

Thyroglossal duct cyst appearing as a midline neck mass at the level of the hyoid bone.

- Thyroglossal duct cysts are nearly always connected to hyoid bone.
- Uncommonly, TDCs may occur lateral to midline but do not occur in the lateral portion of the neck (i.e., lateral to jugular vein).
- Clinical presentation of an uninfected TDC usually that of asymptomatic midline neck mass:
 - Mass typically moves upward on swallowing.
 - Inflamed or infected TDCs may be associated with tenderness and pain.
 - Extrinsic airway compression in neonates with apnea, cyanosis, and respiratory compromise may uncommonly occur.
- Radiology:
 - Midline round or elongated cystic lesion
 - Expansion and/or destruction of the cartilaginous structure of the hyoid bone may be seen.
 - Seldom contains enough thyroid follicular tissue to be seen on scintiscan
 - Presence of nodular soft tissue excrescences in a midline cystic neck mass on CT scan may suggest the possibility of a papillary carcinoma arising in a thyroglossal duct cyst.

Pathology

Fine-Needle Aspiration Biopsy (FNAB)

- Smears from thyroglossal cysts are low in cellularity, and inflammatory cells are more numerous than epithelial cells.
- Squamous or respiratory epithelium may be identified.

Fig. 27-7. Thyroglossal duct cyst.

Thyroglossal duct cysts. **A** and **B**, Contrast-enhanced, axial, CT images demonstrate a well-circumscribed, rim-enhancing cystic mass along the path of the thyroglossal duct from the foramen cecum/base of tongue (**A**) to the infrahyoid neck (**B**). **C**, Axial, T2-weighted, MR image from another patient, a neonate, demonstrates a small hyperintense lesion in the midline of the tongue base at the expected location of the foramen cecum (arrow). (From Som and Curtin: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 28-126, page 1726.)

Fig. 27-8. Thyroglossal duct cyst.

Thyroglossal duct cyst resection specimen (Sistrunk procedure) includes an en bloc removal of the cyst, the middle third of the hyoid bone, and the suprahyoid tract.

- Inflammatory cells, especially mature lymphocytes, are frequently present.

Gross

- Smooth walled cystic structures usually measure less than 2 cm.
- Cystic content includes clear mucinous fluid; infected cysts contain purulent material.

Histology

- Epithelial-lined cystic proliferation within (hyoid) bone
- In noninflamed cysts, the cysts lining is respiratory (columnar) epithelium but may also include squamous epithelium.
- In presence of inflammation, cyst lining undergoes metaplastic change and is lined by squamous epithelium.
- Presence of thyroid tissue in cyst wall varies and may be dependent on the extent of specimen sampling:
 - In general, thyroid tissue can be found in more than 60% of the cases.
 - Absence of thyroid tissue does not exclude diagnosis.
- Thyroid tissue may be normal, hyperplastic, and nodular or neoplastic (see below).

Fig. 27-9. Thyroglossal duct cyst.

A, Low magnification showing the presence of an epithelial lined cyst within (hyoid) bone. **B**, At higher magnification the cyst is variably lined by squamous epithelium and ciliated respiratory epithelium (mid lower); note the presence of benign thyroid tissue (colloid-filled follicles) within the cyst wall. The presence of thyroid tissue in cyst wall varies and may be dependent on the extent of specimen sampling. The absence of thyroid tissue does not exclude diagnosis.

Fig. 27-10. Papillary thyroid carcinoma in thyroglossal duct cyst.

A, Axial contrast-enhanced CT scan shows a midline cyst just caudal to the level of the hyoid bone. Within the cyst is an enhancing nodule and there is some infiltration of the adjacent strap muscles. This was a papillary thyroid carcinoma within a thyroglossal duct cyst. At surgery, there was extension of the tumor into the strap muscles. **B**, Axial CT scan shows a lobulated, midline, cystic mass involving the strap muscles and bulging back into the larynx. Small calcifications are present within the mass. **C**, Axial CT scan of another patient shows a cystic midline mass attached to the hyoid bone with speckled calcifications within it. Axial T2-weighted (**D**) and T1-weighted, fat-suppressed, contrast-enhanced (**E**) images of this patient show the calcified region within the mass has a low-to-intermediate T2-weighted signal intensity and it enhances. At surgery this was a papillary thyroid carcinoma within a thyroglossal duct cyst with extension of the tumor into the strap muscles. (From Som and Curtin: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 37-45, page 2264.)

Fig. 27-11. Papillary thyroid carcinoma in thyroglossal duct cyst.

Papillary thyroid carcinoma arising in thyroglossal duct cyst. **A**, *Left panel*, Proliferation within the hyoid bone that includes colloid-filled follicles. *Right panel*, Papillary fronds with fibrovascular core. **B**, At higher magnification nuclear features diagnostic for papillary thyroid carcinoma are present.

- Secondary retrogressive changes may be present, including:
 - Fibrosis
 - Chronic inflammatory cell infiltrate
 - Squamous metaplasia that may be focal or extensive

Differential Diagnosis

- Thymic cyst
- Metastatic (cystic) papillary thyroid carcinoma
- Laryngocele
- Branchial cleft cyst
- Squamous cell carcinoma:
 - Presence of extensive squamous metaplasia may raise concern for possible presence of squamous cell carcinoma but metaplastic foci typically bland-appearing lacking cytomorphic features of carcinoma

Treatment and Prognosis

- Surgery is preferred treatment:
 - Sistrunk procedure includes en bloc surgical resection of cyst, middle third of the hyoid bone, and suprahyoid tract up to base of tongue (foramen cecum).
- Adequate surgery results in cure with low to no recurrences:
 - Reported recurrence rates range from 0% to 11%.
 - Extended surgical procedures prevent recurrence.
- Benign and malignant neoplasms may occur in the setting of a thyroglossal duct cyst:
 - Benign tumors include follicular adenoma.

- Development of a carcinoma in a thyroglossal duct cyst is rare:
 - Most carcinomas that develop in this setting are papillary carcinomas.
 - Rare examples of follicular carcinoma (oncocytic, nononcocytic types), undifferentiated (anaplastic) thyroid carcinoma, squamous (epidermoid) carcinoma, and adenosquamous carcinoma
 - Squamous (epidermoid) carcinoma and adenosquamous carcinoma in all probability arise from cyst lining rather than from thyroid cell component.
- C-cell-related lesions, including medullary thyroid carcinoma, do not occur in thyroglossal duct cysts due to the different embryologic derivation of the C-cells.
- Papillary thyroid carcinoma arising in the setting of a thyroglossal duct cyst:
 - Occur more commonly in women than men
 - Occur over a wide age range (first through eighth decades of life)
 - Are of usual morphologic type:
 - Variant types may include follicular variant, tall cell variant.
 - Similar (excellent) prognosis to that of papillary thyroid carcinoma arising in thyroid gland proper
 - May recur or metastasize and rarely may be lethal
 - Detailed evaluation of thyroid gland proper indicated
 - No clear consensus exists regarding optimal management, which may include:

- Sistrunk procedure
- Sistrunk procedure with total thyroidectomy
- Sistrunk procedure with total thyroidectomy and neck dissection
- Following total thyroidectomy:
 - Approximately one third may have concomitant papillary thyroid carcinoma in thyroid gland proper:
 - Often represent incidental papillary microcarcinomas
 - Nodal cervical metastasis may be present.
 - Such findings suggest that ultrasonography and, if warranted, fine-needle aspiration biopsy should be performed, and in presence of suspected lesion in thyroid gland proper and/or lymph node, Sistrunk procedure with total thyroidectomy, and neck dissection should be performed.
- In cases of lateral aberrant thyroid with associated lymphocytic thyroiditis, presence of a prominent lymphoid infiltrate gives the overall impression that the tissue is from a lymph node potentially leading to mistaken diagnosis of metastatic carcinoma:
 - Nodal tissue has subcapsular sinuses, whereas thyroid tissue with lymphocytic thyroiditis does not.
- Aberrant thyroid tissue shows histopathologic changes similar to those seen in thyroid gland proper (e.g., lymphocytic thyroiditis, goitrous changes).
- BRAF V600E mutation analysis reported in limited number of aberrant thyroid tissue was negative.
- Mechanical implantation of thyroid tissue (normal or hyperplastic) refers to presence of thyroid tissue in the neck due to surgical intervention or trauma:
 - Unattached to thyroid gland may be the result of prior surgery or accidental trauma
 - In such instances, there usually is a prominent fibrotic reaction and/or suture material seen in association with the thyroid tissue.

Parasitic Nodule

Definition: Refers to occurrence of thyroid nodule in the neck in which there is no connection to thyroid gland due to ablation of this connection or lack of identification of connection to the main gland:

- Usually an expression of nodular hyperplasia (adenomatoid nodules) or nodular chronic lymphocytic (Hashimoto) thyroiditis
- Less often expression of diffuse hyperplasia (i.e., Graves disease)

Synonyms: Sequestered thyroid nodule or accessory nodule

- Lateral aberrant thyroid: former term used for thyroid tissue lateral to jugular vein:
 - Most of such cases, especially in lymph nodes, represent metastatic papillary thyroid carcinoma.
 - Many of such previously termed cases represent parasitic nodules.
- “Aberrant” tissue may be connected to the thyroid by a thin fibrous strand that may or may not be appreciated by the surgeon or the pathologist, or there may not be a discernible attachment to thyroid gland proper.
- May occur in the mediastinum as part of mediastinal nodular hyperplasia (goiter)
- Stipulations for diagnosis of parasitic nodule include:
 - Aberrant thyroid tissue should be located in same fascial plane as thyroid gland.
 - Thyroid tissue not identified in relationship to a lymph node:
 - If thyroid tissue is seen within lymph node parenchyma, then it should be considered as metastatic carcinoma.
 - Presence of subcapsular sinuses assists in identifying given structure as being a lymph node.

Thyroid Tissue in Lymph Nodes

(Figs. 27-12 and 27-13)

- Controversial issue whether benign thyroid inclusions in lymph nodes truly exist or whether all thyroid tissue located within a lymph node, irrespective of the nodal site or the degree of tumor differentiation, represents metastatic carcinoma from a primary thyroid tumor
- In theory, it is conceivable that benign thyroid inclusions in lymph nodes may occur similar to nevus cell inclusions or salivary gland inclusions within lymph nodes; however, to consider a possible diagnosis of benign thyroid inclusion, strict criteria must be met, including:
 - Lymph node is located in midline, near midline, or medial to jugular vein.
 - Thyroid tissue is limited in extent (only a few follicles) located in nodal capsule and not found in subcapsular sinus(es), does not replace nodal parenchymal tissue, and/or is not found in multiple lymph nodes.
 - Inclusions are cytologically bland without histologic evidence to support diagnosis of metastatic papillary thyroid carcinoma.
 - Absence of psammoma bodies
 - Primary thyroid carcinoma is not present; however, this does not entirely exclude an occult primary tumor with metastatic (nodal) disease.
- Even if the above criteria are met, a diagnosis of benign thyroid inclusions in lymph nodes should be made with caution as, in all likelihood, these foci

Fig. 27-12. Benign nodal thyroid inclusions.

(Benign) thyroid inclusions in a midline lymph node.

A, Very few colloid-filled follicles are identified in the nodal capsule and not in subcapsular sinus(es) and/or in nodal parenchyma. **B,** At higher magnification the follicular cells are cytologically bland without histologic evidence to support diagnosis of metastatic papillary thyroid carcinoma.

represent metastatic papillary thyroid carcinoma (even in absence of cytomorphologic evidence of thyroid papillary carcinoma):

- A diagnosis of metastatic carcinoma likely would result in thyroidectomy (lobectomy or total thyroidectomy).
- Primary carcinoma often located in ipsilateral thyroid lobe but metastatic carcinoma in central compartment nodes may arise from anywhere in thyroid gland.
- Primary carcinoma may be small and clinically undetectable.
- Histologic identification of primary thyroid carcinoma may require exhaustive sectioning and histologic evaluation of resected thyroid gland, including:

- Multiple levels of paraffin blocks
- In absence of identifying primary carcinoma, “flipping” paraffin blocks and cutting multiple levels may be necessary
- Even following exhaustive search primary carcinoma may not be detected, which does not exclude the primary residing in thyroid gland proper nor “rule in” benign thyroid inclusions.
- Diagnosis of metastatic papillary thyroid carcinoma can be made if:
 - Thyroid tissue is located in a lymph node that is lateral to jugular vein and/or there is cytomorphologic evidence (i.e., nuclear features) diagnostic for papillary thyroid carcinoma irrespective of location of lymph node(s).
- Diagnostic confusion may occur in setting of parasitic nodule (see above) with chronic lymphocytic (Hashimoto) thyroiditis:
 - In this setting, prominent lymphocytic thyroiditis, which may include germinal centers, could simulate the appearance of a lymph node so that thyroid tissue is considered as metastatic to a “lymph node.”
 - In contrast to lymph nodes, this tissue does not have subcapsular spaces, and thyroid follicular epithelium has changes associated with chronic lymphocytic (Hashimoto) thyroiditis, including cytoplasmic oxyphilia with enlarged nuclei lacking the constellation of cytomorphologic (nuclear) features of papillary thyroid carcinoma.
 - Immunohistochemistry:
 - In absence of known primary cancer, immunoreactivity for thyroglobulin confirms thyroid origin and differentiates metastatic thyroid carcinoma from carcinomas that may show histologic similarities to thyroid tumors, including salivary gland tumors (e.g., acinic cell carcinoma, mammary analogue secretory carcinoma, others) and non-head and neck cancers (e.g., lung, others).
 - Unlike thyroglobulin, TTF1 is not uniquely limited to lesions of thyroid gland origin.
 - Papillary thyroid carcinoma (and to a much lesser extent other thyroid type carcinomas) may originate in ovarian teratoma (i.e., struma ovarii), but such occurrences are rare and even rarer to metastasize to the head and neck (see below).
- Limited diagnostic utility in differentiating benign thyroid inclusions from metastatic papillary thyroid carcinoma:
 - Benign inclusions and metastatic carcinoma are immunoreactive for thyroglobulin, TTF-1, PAX8

Fig. 27-13. Metastatic papillary thyroid carcinoma.

A and **B**, Isolated “naked” psammoma bodies in the subcapsular sinuses of involved lymph nodes. **C** and **D**, In other lymph nodes, viable foci of metastatic papillary thyroid carcinoma including psammoma bodies were identified. In the presence of isolated psammoma bodies in lymph nodes chances are high that viable papillary carcinoma will be identified in the same or other resected lymph nodes. The primary focus of the metastatic carcinoma was found in the ipsilateral thyroid lobe (not shown).

- There may be some utility to using HBME1 (and CK19, galectin 3) in trying to differentiate benign inclusions (should be HBME1 negative) from metastatic papillary thyroid carcinoma (should show strong membranous HBME1 staining), but such staining is not sensitive or specific (see more detailed discussion in Chapter 28 under Papillary Thyroid Carcinoma).
- *BRAF* and/or *RET/PTC* mutational analysis could assist in discriminating thyroid follicular epithelium in association with chronic lymphocytic thyroiditis (*BRAF* or *RET/PTC* negative) from foci of papillary thyroid carcinoma (*BRAF* or *RET/PTC* positive).
- “Naked” psammoma bodies in lymph nodes:
 - Psammoma bodies are round calcific concretions showing concentric laminations.
 - Not entirely specific for papillary thyroid carcinoma but are exceptionally rare in benign thyroid diseases and in other thyroid carcinomas:
 - Represent important diagnostic clue to presence of papillary thyroid carcinoma
 - Found in approximately 50% of papillary thyroid carcinomas
 - Particularly common in tumors with classic papillary architecture and considered essentially pathognomonic for papillary thyroid carcinoma
 - Often seen in association with lesional cells showing typical nuclear features for papillary thyroid carcinoma but may be identified as

isolated finding in thyroid parenchyma, in areas of inflammation, and/or in fibrotic areas without associated lesional cells that may be referred to as “naked” psammoma bodies

- If present in lymph nodes chances are high that papillary carcinoma is present in lymph node with primary focus of carcinoma in (ipsilateral) thyroid lobe
 - Primary carcinoma may be very small and difficult to detect clinically and histologically.
- Should be noted that presence of psammoma bodies is not limited to thyroid cancer and can be seen in association with other primary malignancies, including salivary gland tumors (e.g., acinic cell carcinoma, mammary analogue secretory carcinoma, polymorphous low-grade adenocarcinoma, cribriform adenocarcinoma of minor salivary glands, others), as well as primary non-head and neck malignant tumors (e.g., lung, ovary, thymus, others)
- Generally considered rare for a primary salivary gland carcinoma to metastasize as a clinically occult primary carcinoma
- Although presence of “naked” psammoma bodies in lymph nodes is highly correlated to metastatic papillary thyroid carcinoma, simply because there are accompanying psammoma bodies in lymph nodes does not necessarily equate to a diagnosis of metastatic (primary) thyroid carcinoma:
 - Histologic evidence in support of a thyroid origin and/or immunohistochemical confirmation (i.e., thyroglobulin) required
- When thyroid gland enters the thoracic inlet, reduced pressure on inspiration may accelerate the migration:
 - Clinically, inferior part of gland cannot be determined due to its location behind the manubrium.
- Goiters with intrathoracic extension usually lead to development of earlier and more severe symptoms:
 - Compression of trachea, esophagus, and great vessels more likely to occur in confined space or tracheal inlet
 - Exacerbation of symptoms may occur at night when patient is supine or lies on one side or other, or by certain positions that increase tracheal compression.
 - Occlusion of thoracic outlet may occur when arms extended over head
 - Referred to as Pemberton sign
 - Results in obstruction of venous return from head and neck region in visible venous distension over neck and plethoric changes in color of facial skin that may be associated with difficulty breathing and/or rarely syncope
- Intrathoracic extension occurs primarily into anterior mediastinum:
 - Approximately 10% located in posterior mediastinum
- Radiology:
 - On chest x-ray, an anterior mediastinal mass may be seen; thyroid scans (^{123}I) may show functional activity as well as the inferior extension of the thyroid gland.
 - Computed tomography and magnetic resonance imaging are extremely useful tools in the diagnosis of mediastinal goiters; features of a mediastinal mass seen on computed tomography (CT) that favor or suggest a thyroid origin (substernal goiter) include:
 - Anatomic continuity with the cervical thyroid
 - CT density greater than muscle
 - A rise in CT density and prolonged enhancement following contrast injection (≥ 2 minutes)
 - Multiple areas of calcification and proximity of the mass to the trachea
 - Tc-99m pertechnetate scintigraphy with and without oral administration of potassium perchlorate (KCLO₄) administration is an accurate and cost-effective imaging method to diagnose retrosternal goiter:
- Most mediastinal goiters are benign (adenomatoid nodules):
 - Thyroid malignancies can be seen in a mediastinal thyroid tissue and include:
 - Papillary carcinoma (microcarcinoma, classic type, follicular variant, others), follicular

Mediastinal Thyroid (Substernal Goiter)

Definition: Presence of goitrous thyroid extending from thyroid gland proper into the mediastinum (substernal or retrosternal):

- Most widely used definition is one in which >50% of total bulk of thyroid gland extends into mediastinum.
- Additional consideration for substernal goiter is one that descends below plane of thoracic inlet.

Clinical

- Clinical parameters, including treatment of substernal goiter, are similar to those goiters (adenomatoid nodules) situated within the normally located thyroid (see later in this chapter).
- As multinodular goiter enlarges, it has a tendency to move inferiorly due to fascial planes favoring this migration.

carcinoma, and undifferentiated (anaplastic) carcinoma

- Mediastinal goiters generally do not respond to thyroid suppression and require surgical removal:
 - Further, due to the risk of sudden enlargement with possibility of airway compression or obstruction, intrathoracic goiters should be surgically removed.

OVARIAN THYROID TISSUE

Definition: Thyroid tissue differentiation occurring in setting of an ovarian teratoma.

Struma Ovarii

(Figs. 27-14 through 27-16)

Definition: Ovarian teratomas in which thyroid tissue is predominant (at least 50%) or sole tissue component.

Clinical

- Presence of thyroid tissue within an ovarian teratoma varies and may be a function of adequate sampling:
 - Benign thyroid tissue occurs in from 5% to 15% of mature ovarian teratomas.
- May occur in a wide range of ages including from second to ninth decades of life
- Clinical presentation (of an ovarian teratoma, in general) is that of an abdominal mass and acute abdominal pain; rarely, may initially be detected as an ovarian mass complicating pregnancy.
- Functional abnormalities may occur and include:
 - Hyperthyroidism
 - Rarely struma ovarii may coexist with Graves disease.
 - Patients may present with ascites that, in the presence of an ovarian mass, may be suspicious for ovarian carcinoma.
 - Ascites and hydrothorax (“pseudo-Meig syndrome”) may occur and may be associated with raised serum CA 125 levels.
- Bilaterality may occur in 5% to 10% of cases.
- Radiology:
 - CT shows cystic components with slightly high density.
 - MRI findings include the presence of multilocular cystic mass with a variable signal intensity within loculi.
 - Loculi or small cysts within septations may show low signal intensity on T1-weighted images and very low signal intensity on T2-weighted images.
 - Gd-DTPA enhanced T1-weighted images may show the presence of thick septations and locally

Fig. 27-14. Struma ovarii.

A, Low magnification showing the presence of ovarian parenchyma (*top*) and presence of thyroid parenchyma (*bottom right*) composed of colloid-filled follicles.

B and **C**, Thyroid parenchyma composed of a benign follicular epithelial cell proliferation with features of an adenomatoid nodule.

Fig. 27-15. Proliferative struma ovarii.

Left, Follicular growth pattern with minimal to absent colloid. *Right*, The presence of thyroglobulin immunoreactivity is confirmatory of thyroid follicular epithelial cell tissue.

thickened wall with marked enhancement (corresponding microscopically to thyroid tissue).

Pathology

Gross

- Often resembles nodular goiter, appearing as multiple glistening brown nodules

Histology

- Thyroid tissue may be one of many tissue types of the teratoma representing only a minor component of ovarian teratoma; however, in those instances in which the thyroid tissue predominates (at least 50%) or is the sole component of the teratoma, the designation of struma ovarii is applied.
- Histology of struma ovarii most often is that normal-appearing thyroid follicular tissue or as a multinodular goiter with colloid-filled variably sized follicles lined by flattened follicular epithelial cells:
 - Papillary hyperplasia of follicular epithelium can be seen.
 - Secondary degenerative changes such as fibrosis, cyst formation, and hemorrhage can occur.
- Discrete mass lesions composed of densely cellular thyroid follicles (without evidence of malignancy) may be seen and have been termed proliferative struma ovarii.
- Clear cell and signet ring cell cytoplasmic changes can occur.
- Changes of lymphocytic thyroiditis may occur.
- Immunohistochemistry:
 - Thyroglobulin reactivity:
 - Positive in struma ovarii, as well as in thyroid follicular neoplasms (benign and malignant) that occur in this setting

- Thyroid transcription factor 1 (TTF-1) expressed in follicular epithelial cells, as well as in respiratory epithelium, if present
- Calcitonin, chromogranin, and synaptophysin negative
- Cytogenetics and molecular genetics:
 - Various molecular alterations identified in malignant struma ovarii (see below), including:
 - *RET/PTC*
 - *BRAF*
 - *RAS*
 - *PAX8-PPAR γ*

Thyroid Neoplasms in Struma Ovarii

- Thyroid neoplasms arising in setting of struma ovarii are rare:
 - In theory, any neoplasm affecting the thyroid follicular epithelium proper can occur in setting of struma ovarii.
 - Most common type of thyroid neoplasm to occur in this setting is papillary thyroid carcinoma:
 - May be referred to as malignant struma
 - Most are conventional type and follicular variant; less commonly other variants reported, including tall cell variant
 - Diagnosis is based on finding architectural, but more importantly, on the cytomorphic features of papillary carcinoma.
 - Invasive growth (vascular or stromal) is not required for a diagnosis of papillary carcinoma.
 - Follicular carcinoma may occur in the setting of struma ovarii:
 - In contrast to diagnosis of papillary carcinoma in this setting, a diagnosis of follicular carcinoma is based on presence of capsular or vascular invasion and absence of cytomorphic features of papillary thyroid carcinoma.

Differential Diagnosis

- Metastasis to ovary from a primary thyroid carcinoma:
 - Extraordinarily rare occurrence
 - Synchronous or metachronous papillary thyroid carcinoma within struma ovarii (malignant struma) and thyroid gland reported:
 - Rare case reports
 - Differences in microscopic features, immunohistochemical staining (HBME1, CK19, galectin-3), and molecular genetics (*BRAF V600E*, *RAS*, *RET/PTC*) reported

Treatment and Prognosis

- Treatment for ovarian teratoma including struma ovarii is surgical excision:

Fig. 27-16. Malignant struma.

Papillary thyroid carcinoma in struma ovarii (malignant struma). **A**, Low magnification showing the presence of colloid-filled thyroid follicles (*left*) in ovarian parenchyma (*right*). **B**, Most of the lesion showed a follicular growth pattern in which the follicles are lined by cells showing nuclear features diagnostic for papillary thyroid carcinoma. **C**, Focal papillary architecture was identified. **D**, Metastatic papillary thyroid carcinoma to a mesenteric lymph node; mesothelial cells are readily identified (*arrowheads*).

- Unilateral salpingo-oophorectomy or total abdominal hysterectomy and salpingo-oophorectomy (unilateral or bilateral)
- Surgical removal is curative.
- In setting of benign struma ovarii, if there is a normally situated (cervical) thyroid gland without abnormalities, then surgical intervention relative to the normally situated thyroid gland not indicated
- Treatment for malignant struma ovarii is surgical excision:
 - Unilateral salpingo-oophorectomy or total abdominal hysterectomy and salpingo-oophorectomy (unilateral or bilateral)
 - Total thyroidectomy also performed:
 - Required to treat with radioactive iodine
- Metastatic disease from papillary carcinoma in struma ovarii may occur and include such sites as:
 - Contralateral ovary, peritoneum, regional lymph nodes, liver, and brain
- Overall prognosis associated with malignant thyroid tumors in struma ovarii has been good:
 - 89% 10-year survival
 - 84% 25-year survival
 - Recurrence may occur within months or decades following initial resection.
 - Although unusual, fatalities secondary to widespread metastatic disease have occurred:
 - May occur years following initial diagnosis
 - Long-term follow-up indicated
- Clinical features predictive of biologic malignancy in struma ovarii include:

- Presence of adhesions, peritoneal fluid ($>$ or $=$ 1 L), or a serosal rent
- Pathologic factors predictive of a poorer prognosis in struma ovarii include:
 - Large size ($>$ or $=$ 10 cm), strumal component more than 80%, extensive papillary carcinoma, especially with solid areas, necrosis, and increased mitotic activity (≥ 5 mitoses per 10 high-power fields)
- So-called benign strumatosus has been used for presence of benign thyroid follicular epithelium within the peritoneum:
 - These foci should be considered as representing metastatic thyroid carcinoma.
- Rare instances of non-Hodgkin malignant lymphomas have been reported in struma ovarii.

Strumal Carcinoid (Fig. 27-17)

Definition: Ovarian tumor that includes presence of thyroid tissue admixed with carcinoid tumor:

- In this setting, other teratomatous elements are usually absent.

Clinical

- Majority of women with strumal carcinoids are postmenopausal, but this tumor may occur over a wide age range from the third through eighth decades of life.
- Clinical presentation is similar to that of any ovarian teratoma presenting as an enlarging abdominal mass or identified as an incidental finding on routine gynecologic (or urologic) evaluation.

Fig. 27-17. Strumal carcinoid.

A and B, Thyroid tissue within the ovary (not shown) included foci with trabecular and organoid growth. **C,** At higher magnification the lesional cells are composed of round to oval nuclei with dispersed (stippled) appearing nuclear chromatin. **D,** Lesional cells are immunoreactive for synaptophysin.

- Other (uncommon) clinical presentations may include:
 - Constipation, pain on defecation, virilization, hirsutism, symptoms related to function of the thyroid component, and association with multiple endocrine neoplasia 2A:
 - Peptide YY found in association with symptoms of constipation
 - Extremely rare occurrence of carcinoid syndrome has been reported.
 - Similarly rare occurrence of carcinoid heart disease has been reported.
 - Rarely reported in association with struma ovarii and malignant transformation, including follicular variant of papillary thyroid carcinoma, mucinous cystadenomacarcinoma, and strumal carcinoid
- Histogenesis of strumal carcinoid remains controversial:
 - Most likely, histologic elements of this tumor arise from a common progenitor cell such as gives rise to the ovarian teratoma (i.e., endodermal germ cell)
 - No evidence to support C-cell origin for carcinoid component
- Calcitonin only rarely identified
- Neurohormonal peptides that can be present include pancreatic polypeptide, glucagon, somatostatin, vasoactive intestinal polypeptide, and substance P.
- Thyroglobulin and TTF-1 negative in carcinoid component but thyroglobulin and TTF-1 reactive in noncarcinoid thyroid follicular component of strumal carcinoid
- Prostatic acid phosphatase (PAP) may be present in carcinoid component:
 - Similar findings as identified in rectal (hindgut) carcinoids
- Electron microscopy:
 - Neurosecretory granules can be seen.

Differential Diagnosis

- Atypical carcinoid:
 - Extraordinarily rare examples reported
 - As compared to (typical) strumal carcinoid tumor shows greater degree of nuclear pleomorphism, higher mitotic rate, and focal necrosis
 - May metastasize including to bone

Treatment and Prognosis

- Treatment is surgical removal.
 - May include:
 - Unilateral salpingo-oophorectomy in younger-age patients
 - Bilateral oophorectomy and hysterectomy in older-age patients
- Prognosis:
 - Considered excellent following surgical removal even in presence of metastatic tumor
 - Fatalities have been reported.

Pathology

Histology

- Characterized by presence of normal thyroid follicular tissue admixed with carcinoid tumor:
 - Diagnosis is made as long as both components are present and is not based on whether one or the other predominates.
- Carcinoid component:
 - Trabecular growth
 - Composed of cells with small round to oval nuclei with dispersed (“salt and pepper”) chromatin
 - Rarely, acellular eosinophilic extracellular material representing stromal amyloid deposition is present.
 - Rarely, carcinoid component may be of mucinous type (mucus-secreting cells).
- Follicular epithelial component composed of colloid-filled follicles lined by flat to columnar cells with round to oval nuclei and coarse nuclear chromatin:
 - Birefringent calcium oxalate monohydrate crystals are identified in the colloid material.
- Teratomatous elements, including cutaneous and respiratory epithelium, can be identified.
- A dense fibrous stroma is present.
- Histochemistry:
 - Carcinoid component will be argentaffin and argyrophilic positive.
- Immunohistochemistry:
 - Synaptophysin, chromogranin, NSE, and serotonin positive in carcinoid component

METAPLASIA OF THYROID FOLLICULAR EPITHELIUM

Definition: A benign process in which there is a phenotypic alteration from one cell type to another cell type.

Squamous Metaplasia

(Figs. 27-18 and 27-19)

- Benign process in which the normal follicular epithelium changes to one with squamous cell features
- Can occur in a wide variety of settings (Box 27-2)
- Clinical features in which squamous metaplasia occurs based on the pathologic process in which it appears
- Most often, squamous metaplasia of thyroid follicular epithelium seen in setting of lymphocytic thyroiditis and in adenomatoid nodules with retrogressive changes, the latter occurring spontaneously or

Fig. 27-18. Squamous metaplasia in the thyroid gland.

A, Foci of squamous metaplasia (*arrows*) seen in association with a small adenomatoid nodule (*top*) and background of chronic lymphocytic thyroiditis. **B,** At higher magnification the metaplastic foci include individual cell keratinization and intercellular bridges.

secondary to traumatic event such as a prior fine-needle aspiration biopsy

- Not infrequently may be seen in association with papillary thyroid carcinoma (with or without lymphocytic thyroiditis)
- Alternative theory to squamous metaplasia of follicular epithelial cells is origin from solid cell nests of ultimobranchial derivation:
 - Bulk of evidence favors follicular epithelial cell origin for presence of squamous cells in thyroid gland.

Pathology

- Histology of squamous metaplasia includes:
 - Bland appearance in which nests of cells are round to oval (including “morule” formation) without infiltrative growth

Fig. 27-19. Squamous metaplasia occurring in association with papillary thyroid carcinoma.

A, Foci of squamous metaplasia (*arrows*) are seen in association with cystic papillary thyroid carcinoma and background of chronic lymphocytic thyroiditis.

B, Squamous metaplasia (*arrowhead*) has bland cytomorphic appearance in which nests of cells are round to oval (“morule” formation) without infiltrative growth. The metaplastic focus is located adjacent to a cystic epithelial proliferation (*left*) lined by cells showing nuclear features diagnostic for papillary thyroid carcinoma.

- Keratinization and intracellular bridges can be seen.
- Basaloid cells may be present.
- Cytologic atypia absent, including:
 - Lack of significant pleomorphism and atypia
 - Low nuclear-to-cytoplasmic ratio
 - Mitotic figures can be seen but are limited in number and atypical mitoses not present.
- Absence of associated mucous cells
- Extent of squamous metaplasia may be:
 - Focal (more common)
 - Extensive (less common)

BOX 27-2 Thyroid Lesions That May Have Associated Squamous Metaplasia**Non-Neoplastic**

- Nodular goiter (adenomatoid nodules) with or without retrogressive changes
- Chronic (focal) lymphocytic thyroiditis
- Hashimoto thyroiditis and variants
- Following fine-needle aspiration biopsy or incisional biopsy
- Developmental:
 - Solid cell nests (squamous foci)
 - Thymic rests (Hassall corpuscles)

Neoplasms

- Papillary thyroid carcinoma
- Diffuse sclerosing variant of papillary thyroid carcinoma
- Primary squamous cell carcinoma
- Primary mucoepidermoid carcinoma
- Metastatic squamous cell carcinoma to the thyroid
- Teratoma

- Immunohistochemistry:
 - Cytokeratin (AE1/AE3) positive
 - Variable reactivity for thyroglobulin, TTF-1 may be negative
 - p63 positivity can be seen with predominant positivity at periphery of cell nests.
 - Calcitonin, chromogranin, carcinoembryonic antigen (CEA), and high molecular weight keratin (e.g., 34βE12) negative
- Mutational analysis:
 - *BRAF* and *RAS* negative

Differential Diagnosis

- Primary thyroid squamous cell carcinoma and mucoepidermoid carcinoma (MEC) (see Chapter 28):
 - Both thought to arise from squamous metaplasia of thyroid follicular epithelial cells
 - Majority of cases of squamous metaplasia lack the cytologic atypia and/or infiltrative growth of squamous cell carcinoma.
 - Absence of admixture of epidermoid cells, mucous cells, and intermediate cells allows differentiation from MEC.

Treatment and Prognosis

- Predicated on setting in which the squamous metaplasia occurs

Oncocytic (Oxyphilic) Metaplasia
(Figs. 27-20 and 27-21)

Definition: Oncocytic (oxyphilic) metaplasia is derived from the Greek word meaning “swollen” and results from an increase in mitochondrial content of a cell.

Fig. 27-20. Oncocytic (oxyphilic) metaplasia.

A, Chronic lymphocytic (Hashimoto) thyroiditis with follicular epithelial cells showing oncocytic metaplasia. **B,** At higher magnification oncocytic metaplasia is characterized by the cells with brightly eosinophilic and granular cytoplasm. The oncocytic cytoplasmic changes are associated with nuclear enlargement and pleomorphism, some degree of nuclear clearing, and the presence of prominent eosinophilic nucleoli. Despite the nuclear enlargement, the nuclei remain round with coarse chromatin pattern lacking features of papillary thyroid carcinoma.

- By light microscopy, an oncocytic cell is one that has prominent granular eosinophilic-appearing cytoplasm.
- Oncocytic change not limited to the thyroid but occurs in many nonendocrine organs (e.g., salivary glands, others) as well as in other endocrine organs (pituitary gland, parathyroid gland, adrenal glands).

Synonyms: Hürthle cell is a designation restricted to oncocytic cells in thyroid gland; in all other

Fig. 27-21. Cellular adenomatoid nodule with oncocytic (oxyphilic) metaplasia.

A, Oncocytic cells are prone to retrogressive changes as may occur following a fine-needle aspiration biopsy that may include papillary architecture (*arrowhead*), necrosis, and hemorrhage. **B**, Follicular cells with oncocytic metaplasia characterized by the cells with brightly eosinophilic and granular cytoplasm adjacent to areas of necrosis and hemorrhage.

(extrathyroidal) sites, use of the terms oncocyte or oxyphilic cell interchangeable

- Several points regarding the presence of oncocytic cells include:
 - Hürthle originally described cell now thought to represent the parafollicular cell or C-cell of ultimobranchial derivation and not oncocyte
 - Askanazy originally described oncocytic cell in thyroid gland.
- Use of designation oncocytic cell, oxyphilic cell, or Hürthle cell in relationship to thyroid lesions is purely descriptive and indicative of a type of change in a cell and NOT indicative (in and of itself) of a

BOX 27-3 Thyroid Lesions That May Have Oncocytic Cell Changes

Non-Neoplastic Lesions

- Nodular goiter (adenomatoid nodules)
- Autoimmune thyroiditis
 - Chronic lymphocytic (Hashimoto) thyroiditis
 - Graves disease
- Post-radiation
- Aging

Neoplasms

- Follicular adenoma, oncocytic variant
- Follicular carcinoma, oncocytic variant
- Papillary thyroid carcinoma, oncocytic variant
- Medullary thyroid carcinoma, oncocytic

specific diagnosis or of any specified biologic behavior:

- Too often, clinicians are under the assumption that a “Hürthle cell neoplasm” is malignant and is synonymous with a follicular carcinoma.
 - Erroneous assumption, oncocytic cell changes can be seen in non-neoplastic and neoplastic (benign and malignant) thyroid lesions ([Box 27-3](#))
 - May occur in solid cell nests (oncocytic solid cell nests)

Pathology

- Histologically, an oncocytic cell characterized by presence of an abundant eosinophilic granular-appearing cytoplasm
- Oncocytic cytoplasmic changes:
 - Associated with enlargement of the cell nucleus:
 - This alteration in nuclear size may lead to an erroneous diagnosis of papillary thyroid carcinoma.
 - Diagnostic confusion may be minimized by:
 - Evaluating the setting in which changes are occurring (e.g., presence of a prominent lymphocytic cell infiltrate as seen in chronic lymphocytic thyroiditis)
 - Evaluating for other changes that may support a diagnosis of papillary thyroid carcinoma, in particular constellation of nuclear changes that in addition to nuclear enlargement includes nuclear variation in size and shape, clear to very fine-appearing nuclear chromatin, margination of chromatin along nuclear membrane, nuclear crowding and overlapping, nuclear grooves, and nuclear pseudoinclusions
 - In addition to enlarged nuclei, cytoplasmic oncocytic change is often associated with prominent central-located eosinophilic nucleoli

- Retrogressive changes:
 - Oncocytic cells perhaps due to oxygen-sensitive nature of mitochondria may be easily traumatized, leading to marked degenerative changes following such events as fine-needle aspiration or core biopsy:
 - Degenerative changes may include pseudopapillary or papillary growth, infarction, necrosis, and hemorrhage.
- Clear cell changes in follicular epithelial cells represent a degenerative process and may be associated and perhaps arise from oncocytic metaplasia.
- Special stains for mitochondria include:
 - Phosphotungstic acid hematoxylin (PTAH): red granular appearance
 - Novelli stain: dark purple appearance
- Immunohistochemistry:
 - Cytokeratin and vimentin positive
 - Weakly thyroglobulin reactive; TTF1 positive
 - Synaptophysin, chromogranin, and calcitonin negative
- Electron microscopy:
 - Cytoplasm filled with mitochondria showing abnormalities in size, shape, and content
- No specific treatment:
 - Treatment and prognosis are predicated on the setting in which the oxyphilic cell changes are seen.

“INCLUSIONS” IN THYROID GLAND

- Embryologic development of the thyroid gland in association with the branchial and pharyngeal pouches allows for incorporation of other branchial and pharyngeal pouch-derived endodermal and mesodermal structures within the thyroid gland.

Intrathyroidal Parathyroid Tissue, Thymic Tissue, Salivary Gland Tissue (Fig. 27-22)

- Branchial and pharyngeal pouch endodermal structures found within thyroid gland include:
 - Parathyroid tissue, thymic tissue, and salivary gland tissue
- Presence of these heterotopic tissues is generally an incidental finding and not cause for surgical removal of thyroid gland.
- Heterotopic parathyroid tissues found within substance of thyroid gland (intrathyroidal) and not outside the thyroid gland (beyond the capsule)
 - Finding parathyroid tissue outside gland reflects inadvertent surgical removal of parathyroid gland(s) at time of thyroid gland resection.

Fig. 27-22. Intrathyroidal thymic tissue.

A, Clusters of predominantly lymphoid cells (*arrows*) within the thyroid gland. **B**, At higher magnification Hassall corpuscles were identified confirming the presence of thymic tissue.

- Incidental parathyroidectomy not uncommon (13.8%) after thyroidectomy and usually not associated with postoperative biochemical hypocalcemia
- In theory, any pathologic process that affects these tissues in their normal anatomic locations may occur when they are found within thyroid tissue; however, in general, histologic appearance of heterotopic tissues is within normal limits and pathologic changes of these tissues (i.e. hyperplasia, neoplasia) are rare:
 - Intrathyroidal hyperfunctioning parathyroid glands can occur.
 - Hyperparathyroidism related to these intrathyroidal parathyroid glands most often due to a parathyroid adenoma and, less often, due to an intrathyroidal parathyroid carcinoma or hyperplasia

- Intrathyroidal thymic-related neoplasms and salivary gland tumors are rare.
- Assessment for patients with hyperparathyroidism may include preoperative noninvasive imaging studies, including neck ultrasound, nuclear medicine scan (technetium-99m-pertechnetate uptake), neck and mediastinal computed tomography scan, and neck and mediastinal magnetic resonance imaging that may localize parathyroid lesions within thyroid gland.
- At times, it may be difficult to histologically differentiate thyroid tissue from parathyroid tissues:
 - Overlapping histomorphologic features of thyroid and parathyroid tissues may include:
 - Clear cell or oncocytic cytoplasmic changes
 - Presence of follicle formation with luminal colloid-like material
 - Features of parathyroid tissue that may be of assistance in differentiating it from thyroid follicular cells include:
 - Overall smaller cell size
 - Hyperchromatic nuclei
 - Sharp cell borders
 - Clear cytoplasm
 - Mixture of different cell types (chief cells, oncocytic cells, clear cells)
 - More pronounced nesting and/or trabecular growth pattern
 - More delicate vascular pattern
 - Presence of parathyroid hormone, parafibromin, synaptophysin, and chromogranin with absence of thyroglobulin immunoreactivity
- Histologic identification of thymic tissue (presence of Hassall corpuscles) and salivary gland parenchyma usually not problematic

Intrathyroidal Branchial Cleft-Like (Epithelial/Lymphoepithelial) Cysts (Figs. 27-23 and 27-24)

- Considered uncommon
- Predominantly occur in adults
- Majority of these cysts are incidentally found in thyroid glands removed for other reasons; occasionally, cysts may attain large sizes presenting as thyroid mass.
- Clinically detectable cysts may appear as a “cold” nodule on thyroid scan and rarely as a “hot” nodule.
- Radiographic (sonographic) imaging may suggest thyroid neoplasm.
- Histogenesis:
 - Due to histologic similarities to branchial cleft cysts, these intrathyroidal cystic structures have been postulated as being of branchial cleft derivation; however, histogenesis not known.

Fig. 27-23. Intrathyroidal branchial cleft-like (epithelial or lymphoepithelial) cysts.

A, Scattered cystic structures are seen (*upper right*) in a background of changes of chronic lymphocytic (Hashimoto) thyroiditis. **B**, The cysts are usually lined by squamous epithelium (*left*) but may include ciliated respiratory epithelium (*right*). These findings were identified in a lateral thyroid lobe rather than in more central (isthmic) portions of the gland, making thyroglossal duct origin less likely.

- Among the considerations is that these intrathyroidal cysts:
 - Part of spectrum of changes associated with chronic lymphocytic (Hashimoto) thyroiditis representing secondary changes (i.e., squamous metaplastic foci with cystic change)
 - In support of a metaplastic alteration with associated cyst formation (which we favor) is the fact that:
 - Chronic lymphocytic (Hashimoto) thyroiditis invariably present in thyroid gland in which the intrathyroidal cysts are seen
 - Identical cysts present as incidental findings in cases of lymphocytic thyroiditis.
 - Cystic lesions often are multifocal and bilateral.

Fig. 27-24. Intrathyroidal branchial cleft-like (epithelial or lymphoepithelial) cysts.

A. In this example many more variably sized cysts are identified, some containing amorphous eosinophilic appearing (colloid-like) material. **B.** At higher magnification the cysts were entirely lined by squamous epithelium.

- Acquired representing cystic degenerative changes of a pre-existing lesion (nodule or neoplasm)
- Originate from developmental rests in thyroid such as solid cell nests (SCN), which represent vestiges of branchial cleft-derived ultimobranchial apparatus
 - In support of this consideration is identification of other branchial cleft-derived structures (e.g., parathyroid glands, thymus) in the thyroid gland
- Histologically:
 - Cystic lesions vary in size from small and indistinct to large and dominant.
 - Dense fibrous capsule may separate cystic lesion from surrounding thyroid tissue.

- Cysts predominantly lined by squamous epithelium consisting of one or multiple layers of cells
- Columnar cell (respiratory-type) epithelium can be seen (with or without cilia):
 - May contain goblet cells that stain for mucin
 - Intermixed with squamous epithelium
- Dense lymphocytic cell infiltrate seen deep to cystic epithelial lining and may include lymphoid aggregates with reactive germinal centers
- Cysts almost invariably occur in association with chronic lymphocytic thyroiditis (Hashimoto thyroiditis or nonspecific chronic thyroiditis).
- Immunohistochemistry
 - Cystic epithelial lining:
 - Reactive with cytokeratins and carcinoembryonic antigen (CEA)
 - Nonreactive for thyroglobulin, calcitonin, or chromogranin
- Cysts are of limited biologic concern.

Solid Cell Nests (SCN) (Figs. 27-25 and 27-26)

Synonyms: Solid ultimobranchial apparatus nests; cystic SNC

- Although the subject of debate, SCN probably are cellular remnants of ultimobranchial apparatus.
- SCN generally incidentally found in thyroid glands removed for other reasons
- When found, SCN localize to lateral lobes (posterolateral and posteromedial aspects) reflecting the migration of ultimobranchial apparatus-derived thyroid cells exclusively to lateral thyroid lobes:
 - SCN as well as C-cell hyperplasia and medullary thyroid carcinoma are not found and do not occur in the isthmus portion of thyroid gland.
- SCN are not uncommon and can be found in more than 25% of resected thyroid glands:
 - Identification of SCN is a function of tissue sampling
- SCN are generally of no biologic concern.

Pathology

- Most measure 0.1 mm on average but may attain larger sizes.
- Appear as small, discrete cell nests, cords, or clusters interspersed among thyroid follicles
- Thought to be composed of two cell types, main cells and C-cells:
 - Predominant (main) cells composed of epithelial cells with:
 - Round to oval-shaped cells with elongated to round-appearing nuclei, finely granular nuclear chromatin, and acidophilic cytoplasm

Fig. 27-25. Solid cell nests.

A, B, Solid cell nests in the normal thyroid gland composed small cell nests comprised of epithelial cells with a squamoid (epidermoid) appearance. Neither keratinization (horny pearl formation or individual cell) nor intercellular bridges are found.

- Nuclear grooves may be present.
- Squamoid (epidermoid) differentiation may be present.
 - Keratinization (horny pearl formation or individual cell) and intercellular bridges are not found.
- Cystic change may be present:
 - Referred to as cystic SCN
 - Lined by flattened multilayered epithelium most often with squamoid features and less commonly by ciliated columnar epithelium
 - Dense eosinophilic intraluminal material may be present.
- Rarely, oncocytic cytoplasmic change reported (oncocytic solid cell nests):
 - Acquire mitochondrial alterations similar to those seen in follicular cells and C-cells
- Second less prominent C-cells composed of cells with clear-appearing cytoplasm and round nuclei

Fig. 27-26. Cystic solid cell nests in the normal thyroid gland.

A, Predominantly cystic and focally solid foci within the thyroid gland. **B,** At higher magnification the cystic and solid areas are composed of epidermoid-appearing cells.

- May merge with thyroid follicle to create so-called mixed follicle
- Mucicarminophilic material can be found:
 - Presence of mucosubstances in SCN thought to be degenerative changes of epidermoid cells, possibly representing true endodermal-derived C-cell conglomerates
- Immunohistochemistry:
 - Main cells are:
 - Cytokeratins (AE1/AE3, CAM5.2, CK903 (34βE12), CK7, CK19) positive
 - CK20 negative
 - Strongly express p63, as well as carcinoembryonic antigen
 - Galectin 3 positive
 - Typically negative for thyroglobulin, TTF-1, HBME1, calcitonin, and parathyroid hormone
 - C-cells are:
 - Positive for calcitonin, chromogranin, synaptophysin

- Positive for cytokeratins (AE1/AE3, CAM5.2, and CK 7)
- Thyroglobulin negative
- Focal immunoreactivity for TTF-1 can be found.
- p63 negative
- These findings demonstrate a dual cell population in solid cell nests with main cells of the solid cell nests displaying a basal/stem cell phenotype (p63 and basal cytokeratin positivity) and C-cells showing features of parafoveolar differentiation.
- Cytogenetics and molecular genetics:
 - Single case of SNC hyperplasia reported to demonstrate *BRAF*(V600E) mutation and *BRAF*(G593D) mutation
 - Supporting histogenetic link between main cells of SNC and papillary thyroid carcinoma
 - Suggesting solid cell nest hyperplasia as precursor lesion of papillary thyroid carcinoma

Differential Diagnosis

- Papillary thyroid carcinoma
- Medullary thyroid carcinoma

MESENCHYMAL-DERIVED “INCLUSIONS” IN THE THYROID GLAND

- Similar to heterotopic endodermal structures found in thyroid gland, heterotopic mesodermal-derived structures such as fat, muscle, and cartilage can also be identified within thyroid gland.

Fat in the Thyroid Gland (Figs. 27-27 through 27-29)

Synonyms: Hamartomatous adiposity; adenolipomatosis; adipose metaplasia

- Rarely, mature adipose tissue can be found within thyroid gland under normal conditions.
- Mature adipose tissue in thyroid gland can also be found in association with numerous pathologic conditions or lesions, including:
 - Adenomatoid nodules, amyloid goiter, lymphocytic thyroiditis, thyroid atrophy, follicular adenoma (adenolipoma), papillary carcinoma, follicular carcinoma, and rarely, diffuse hyperplasia and dysmorphogenetic goiter
- Presence of (non-neoplastic) mature adipose tissue in thyroid gland is an incidental finding found in excision of gland for other reasons.
- Amount and distribution of mature fat varies from a few adipocytes in a limited portion of gland to substantial collections in multifocal sites and/or diffuse infiltration.

Fig. 27-27. Fat in the thyroid gland.

Mature adipose tissue in normal thyroid parenchyma.

Fig. 27-28. Fat in Hashimoto thyroiditis.

Mature adipose tissue in the setting of chronic lymphocytic (Hashimoto) thyroiditis.

Fig. 27-29. Fat in papillary thyroid carcinoma.

Mature adipose tissue in papillary thyroid carcinoma.

- Adipose tissue is intimately admixed with thyroid tissue and does not appear as a separate, solid mass lesion such as would appear in an adipose neoplasm.
- Mature adipocytes appear as fairly uniform cells with some variation in size and shape that are characterized by presence of clear to vacuolated cytoplasm compressing and eccentrically displacing cell nucleus; nuclei are hyperchromatic without pleomorphism.
- Rarely, foci of extramedullary hematopoiesis may be seen within adipose tissue.
- Mechanism by which mature adipose tissue is found in thyroid gland is not known
 - Some possible explanations include:
 - Embryologic rests
 - Metaplasia from stromal fibroblasts
 - Senile involution
 - True neoplastic component
- Benign and malignant lipogenic tumors of the thyroid gland are extraordinarily uncommon.

Muscle in the Thyroid Gland

(Fig. 27-30)

- Similar to adipose tissue in thyroid glands, presence of skeletal muscle is an incidental finding and may be seen in thyroid gland under normal conditions as well as in variety of pathologic conditions.
- Presence of (non-neoplastic) skeletal muscle in thyroid gland is an incidental finding found in excision of gland for other reasons.

Fig. 27-30. Mature skeletal muscle in the thyroid gland.

Skeletal muscle in the thyroid gland (or vice versa) is typically found in the isthmic portion of thyroid gland or in the pyramidal lobe. The skeletal muscle is intimately admixed with thyroid tissue and does not appear as a separate, solid mass lesion such as would appear in a myogenic neoplasm.

- Skeletal muscle typically found in association with isthmic portion of thyroid gland or pyramidal lobe
- Skeletal muscle is intimately admixed with thyroid tissue and does not appear as a separate, solid mass lesion such as would appear in a myogenic neoplasm.
- Thyroid tissue in skeletal muscle is cytologically benign without findings diagnostic for malignancy.
- Benign and malignant myogenic tumors of the thyroid gland are extraordinarily uncommon.

Cartilage in the Thyroid Gland

(Fig. 27-31)

- As with fat and skeletal muscle, mature cartilage can be found in the thyroid gland (adenochondroma); when found it is as an incidental finding found in glands removed for other reasons.

Fig. 27-31. Cartilage in the thyroid gland.

A, Incidentally identified mature cartilage found in a thyroid gland removed for multinodular goiter. **B**, Chondroid focus occurring as a degenerative phenomenon in the setting of adenomatoid nodules.

- Cartilage in thyroid gland may also occur as a metaplastic process seen in association with some pathologic conditions (e.g., adenomatoid nodules).
- Benign and malignant cartilaginous tumors of the thyroid gland are extraordinarily uncommon.

Pigment and Crystals in the Thyroid Gland

Iron

- Following hemorrhage with release of iron from red blood cells, resorption takes place and iron is converted to hemosiderin, which is stored in cell cytoplasm of phagocytizing cells (macrophages) as well as in thyroid follicular cells.
- In thyroid gland, hemosiderin can be found in virtually all pathologic conditions and represents an incidental finding.
- Reflects secondary phenomenon due to hemorrhage and can follow trauma (e.g., post–fine-needle aspiration biopsy, core biopsy) identified in adenomatoid nodules or various neoplasms
- Hemosiderin may be found in macrophages, within the stromal tissues, or within the follicular epithelial cells:
 - Hemosiderin is readily apparent in hematoxylin- and eosin-stained slides and appears as intracytoplasmic coarse brown to yellow pigment.
 - If necessary, iron stains (Prussian blue, Mallory) can be used to identify iron and distinguish it from other pigments.
- Rarely, iron can be stored in the thyroid as a component of a disorder of iron metabolism rather than a secondary phenomenon due to hemorrhage.
- Most cases of iron deposition not associated with thyroid dysfunction:
 - Uncommonly, secondary hypothyroidism may develop.

Lipofuscin

- Lipofuscin pigment represents degenerative (aging) phenomenon in which there is intracytoplasmic accumulation of small yellow to light brown granular-appearing pigment.
- In thyroid gland, lipofuscin pigment can be seen within follicular epithelial cells.
- True nature of lipofuscin has yet to be determined, but it has been shown to react with:
 - Lipid (Sudan IV) and lipofuscin stains
 - Shows diastase-sensitive, periodic acid-Schiff positive intracytoplasmic material
 - Shows lysosomes by electron microscopy
 - Contains the presence of histidine and tryptophan
 - Iron staining is absent.

- Lipofuscin deposition in thyroid gland is an incidental finding, more often seen in thyroid glands from older individuals.
- There is no evidence to indicate that presence of lipofuscin within any cell, including thyroid follicular cells, causes dysfunction or functional compromise of that cell.

Minocycline-Associated Changes (Black Thyroid) (Fig. 27-32)

- Minocycline, a tetracycline derivative, administered to adults for treatment of various reasons (infections, acne) may cause black pigmentation and discoloration of various sites, including skin and thyroid gland.
 - Thyroid involvement referred to as black thyroid

Fig. 27-32. Minocycline pigment (black thyroid).

A, The pigment appears as granular and black to brown on hematoxylin and eosin stain (arrows). **B**, The intracytoplasmic pigment is positive by argaffin (Fontana) staining.

- Presence of minocycline-related pigmentation of thyroid gland is, by and large, not associated with glandular enlargement (hyperplasia) nor functional abnormalities of gland.
 - Rarely, hypothyroidism may be seen in minocycline pigmentation of thyroid gland.
 - Rarely, follicular adenoma, follicular carcinoma, and papillary thyroid carcinoma may be associated with minocycline-induced black thyroid.
- Minocycline pigment appears within cytoplasm of follicular epithelial cells as granular and black to brown:
 - Pigment can also be seen within follicle lumina as large black to brown deposits admixed with colloid.
- Minocycline shares histochemical, electron microscopic, and elemental analysis features with lipofuscin, including:
 - Positive staining with periodic acid-Schiff (PAS), lipid, and lipofuscin stains
 - Presence of lysosomes and autofluorescence
 - Argentaffin stains (Fontana) may be positive.
 - Iron staining negative
 - Increase in vimentin staining in follicular epithelium compared with normal control thyroid glands
 - Thyroglobulin and ubiquitin staining in follicular epithelium is reduced compared with control thyroid tissues.
- True “makeup” of minocycline pigment is still not fully known; possibilities include:
 - Degradation products of drug combined with lipofuscin
 - Oxidation degradation of the drug
 - Drug interaction and alteration of tyrosine metabolism
 - Lysosomal dysfunction
- Localization of pigment may vary from case to case such that in presence of adenomatoid nodules or an adenoma pigment can be seen:
 - In pathologic component of gland and not surrounding uninvolved thyroid
 - In uninvolved thyroid but not in pathologic component of gland
 - In pathologic component of gland and surrounding uninvolved thyroid parenchyma
- Antidepressant agents may be associated with red pigmentation of thyroid gland felt to be due to lysosomal accumulation of drug.

Crystals in the Thyroid Gland

(Fig. 27-33)

- Intracoloidal crystals are not infrequently found in thyroid gland under normal conditions as well as in a pathologic condition.

Fig. 27-33. Crystals in the thyroid gland.

A, B, Follicular adenoma with intracoloidal crystals of varying size and geometric shapes.

- Finding of intracoloidal crystals not associated with any specific diagnosis and may be found in virtually all thyroid abnormalities:
 - Highest prevalence of crystals occurs in association with benign diseases and is most commonly seen in nodular goiters followed by follicular adenomas.
 - Crystals may be found in association with malignant tumors (e.g., papillary carcinomas, follicular carcinomas), but prevalence is low.
 - Low prevalence of crystals seen in association with Graves disease, lymphocytic thyroiditis, and subacute thyroiditis
- Frequency of finding crystals within thyroid gland appears to increase with age.
- Intrathyroidal crystals are exclusively found within colloid and do not appear within cytoplasm of the follicular epithelial cells or in stromal tissues.
- Crystals may be found by fine-needle aspiration, but occurrence of crystals in thyroid fine-needle cytology is lower than that in histologic specimens.

- Crystals are readily apparent by light microscopy; polarization enhances their detection.
- Crystals vary in size and shape and appear in a variety of geometric shapes.
- Chemical analysis of crystals indicates that they are composed of calcium oxalate.
- Finding intracoloidal crystals may be a function of increasing age and/or disease state.
- A separate population of patients who have increased frequency of intracoloidal crystals are those undergoing hemodialysis for chronic renal failure.
- Occurrence of crystals in normal human thyroid is associated with a low-functional state of the thyroid follicles.

HYPOTHYROIDISM AND HYPERTHYROIDISM

General Considerations: Hypothyroidism

Definition: Disorder in which thyroid gland is unable to synthesize and secrete sufficient amounts of thyroid hormone to meet requirement of brain and peripheral tissues.

Primary hypothyroidism: Thyroid failure that results from disease of thyroid gland, including clinical and pathologic state that results from decreased production and subnormal amount of circulating thyroid hormone; accounts for 99% of all cases of hypothyroidism.

Secondary hypothyroidism: Result of decreased thyroid stimulation by thyroid-stimulating hormone (TSH) due to pituitary disease.

Tertiary hypothyroidism: Result of decreased thyroid stimulation by thyroid-stimulating hormone (TSH) due to a decrease in pituitary stimulation resulting from a deficiency in thyrotropin releasing hormone (TRH).

Central or hypothyrotropic hypothyroidism: Synonyms for secondary and tertiary hypothyroidism.

Primary Hypothyroidism

Clinical

- Most common clinical disorder of thyroid function
- Most often caused by disorder of thyroid gland leading to decrease in thyroidal production and secretion of thyroxine (T_4) and triiodothyronine (T_3) invariably accompanied by increased thyrotropin (TSH) secretion
- May result from diseases or treatments that destroy thyroid tissue or interfere with thyroid hormone biosynthesis
- Causes of hypothyroidism are listed in [Box 27-4](#):
 - Worldwide, iodine deficiency most common cause of hypothyroidism

BOX 27-4 Causes of Hypothyroidism

Primary Hypothyroidism

- Chronic autoimmune thyroiditis (atrophic and goitrous forms)
- Radiation treatment (^{131}I therapy, external radiotherapy to head and neck for nonthyroid malignant disease)
- Surgery (total or subtotal thyroidectomy)
- Iodine deficiency
- Drug-induced (antithyroidal medications: lithium, iodine, and iodine-containing drugs and radiographic contrast material)
- Infiltrative diseases of thyroid (amyloidosis, scleroderma)
- Defective thyroid hormone biosynthesis
- Congenital defects in thyroid hormone biosynthesis
- Developmental abnormalities (thyroid dysgenesis)

Central Hypothyroidism (Secondary and Tertiary Hypothyroidism)

- Pituitary disease (neoplasms, infarcts, trauma)
- Hypothalamic disease (neoplasms, infectious disease, trauma)

Transient Hypothyroidism

- Silent (painless) thyroiditis (including postpartum thyroiditis)
- Subacute thyroiditis
- After withdrawal of thyroid hormone therapy in euthyroid patients

- In areas where iodine intake is adequate, most common causes are chronic autoimmune thyroiditis and radiation-induced hypothyroidism secondary to radioactive iodine treatment of hyperthyroidism.
- Equal gender predilection; may occur in all age groups but more commonly affects adults
- May be clinically overt or subclinical; subclinical hypothyroidism is defined as elevated serum TSH and normal thyroxine (T_4) and T_3 concentrations.
- Clinical manifestations independent of cause:
 - Overt hypothyroidism defined as:
 - High serum TSH concentrations and low serum free T_4 concentrations
 - Many but not all patients have symptoms and signs of hypothyroidism but clinical spectrum of severity may be broad even in overt hypothyroidism such that some patients may have very subtle manifestations of disease (few signs and symptoms), whereas others may have more extreme manifestations (myxedema coma).
 - Subclinical hypothyroidism defined as:
 - High serum TSH concentrations (usually <10 mU/L) and normal serum free T_4 concentrations
 - Patients typically have few or no symptoms and signs of hypothyroidism.

- Clinical symptoms and signs of hypothyroidism include (in no particular order):
 - Fatigue, lethargy, sleepiness, mental impairment, depression, cold intolerance, slow movements, slow speech, hoarseness, bradycardia, dry skin, decreased perspiration, nonpitting edema, anemia, decreased appetite, constipation, weight gain, arthralgia, hyporeflexia, paresthesia, menstrual abnormalities (typically menorrhagia), and infertility
- Three types of clinical evidence suggest hypothyroidism:
 - Symptoms and signs consistent with thyroid hormone deficiency
 - Evidence of diseases, previous treatment, or exposure known to cause thyroid or pituitary failure
 - Presence of disorders associated with increased risk of chronic autoimmune thyroiditis
- Myxedema:
 - Severe hypothyroidism sometimes referred to as myxedema but myxedema is not synonymous with hypothyroidism
 - Represents accumulation of glycosaminoglycans in soft tissues (subcutaneous and other interstitial sites), resulting in nonpitting edema of hypothyroid patients
 - Most common in severe (long-standing) primary hypothyroidism
- Factors potentially influencing clinical features of hypothyroidism include:
 - Patient age:
 - In children and adults effects are potentially reversible.
 - In infants, hypothyroidism may result in irreversible mental and physical retardation (see below, endemic cretinism) unless treatment is initiated early.
 - Presence of other diseases:
 - If there is not generalized destruction of thyroid gland, compensatory increase in TSH secretion may maintain thyroid secretion at near normal levels so that the clinical manifestations of hypothyroidism may remain subclinical for years.
 - Rate at which hypothyroidism develops:
 - Those patients with rapid onset of hypothyroidism have more symptoms than those patients who develop it gradually.
- Laboratory testing:
 - Low serum free thyroxine (T_4) levels and elevated serum thyroid-stimulating hormone (TSH) levels confirm presence of hypothyroidism.
 - Serum triiodothyronine (T_3) concentrations also decline but not frankly low until thyroidal T_3 -secretion and hepatic T_4 -to- T_3 conversion.

- Generalized myxedema:
 - Develops in patients with long-standing, severe generalized thyroid deficiency
 - Clinical features result from glycosaminoglycan accumulation in soft tissues resulting in a full face, nonpitting periorbital and cutaneous edema (most marked around the hands), which does not resorb during recumbency (unlike cardiogenic edema).
 - The soft tissue fluid accumulation is composed of a mixture of mucopolysaccharides, hyaluronic acid, and chondroitin sulfate.
 - Fluid may accumulate in virtually every part of the body, some of these sites in which fluid accumulation occurs due to thyroid deficiency and result in clinical signs and symptoms

Select Clinical Manifestations of Hypothyroidism

- Cardiovascular (myxedema heart):
 - Most common cardiovascular abnormality of hypothyroidism is pericardial effusion
 - Other changes relate to cardiac papillary muscle contractile abnormalities, electrical abnormalities resulting in sinus bradycardia as seen by electrocardiographic changes such as prolonged QT intervals, flattening and inversion of T waves, and in children the so-called mosque sign with a dome-shaped T wave and partially obliterated ST segment.
 - Radiographic findings include cardiomegaly.
 - Incidence of atherosclerotic cardiovascular disease is increased in hypothyroid patients.
- Pulmonary:
 - Direct pulmonary effects, including altered pulmonary function tests, depressed ventilatory drives, pleural effusions, decreased surfactant production in the neonate
 - Indirect pulmonary effects, including phrenic nerve paralysis, congestive heart failure causing pulmonary edema, obesity causing atelectasis, others
- Neurologic manifestations
 - Psychiatric disturbances most prominently depression
 - Adults with acquired hypothyroidism have propensity to develop entrapment neuropathies (e.g., carpal tunnel syndrome).
 - Mental retardation and cretinism well-recognized complications of endemic iodine deficiency and untreated overt congenital hypothyroidism
 - Myxedema coma:
 - Rare syndrome represents severe life-threatening hypothyroidism.
 - Most frequently occurs in elderly women with long-standing hypothyroidism

- More likely to occur in winter months possibly associated with extreme cold
- Other possible precipitating factors include infection, drugs (anesthetics, sedatives, tranquilizers, narcotics, lithium), trauma, cerebrovascular accidents, congestive heart failure.
- Cardinal features include hypothermia and unconsciousness.
- High mortality rates in untreated patients
- Should be viewed as a medical emergency
- Rapid diagnosis with immediate initiation of appropriate therapy is key in preventing death; therapy includes ventilatory support, control of water and electrolyte imbalances, temperature control, administration of hydrocortisone therapy in the presence of coexisting adrenal insufficiency, and initiation of thyroid hormone therapy.
- Renal:
 - Alterations in renal hemodynamics and kidney function resulting in generalized fluid retention
 - Extravascular accumulation of protein-rich fluid (albumin and other proteins) results in weight gain but there is a decrease in the plasma volume and a fall in cardiac output.
- Upper aerodigestive tract:
 - Airway obstruction due to goiter, enlarged tongue, pharyngeal muscle dysfunction
 - Uncommonly myxoid polyps of larynx occur in hypothyroid patients.
- Other manifestations of hypothyroidism include:
 - Infectious complications:
 - Increased susceptibility to infections of respiratory tract, urinary tract, and skin reported in hypothyroid patients
 - Hematologic:
 - Anemia is common in hypothyroidism (seen in up to 30% to 40% of patients).
 - Anemia most often normo- or macrocytic and normochromic and represents a normal physiologic response:
 - Thyroid hormone has a stimulatory effect on erythropoiesis via erythropoietin.
 - Deficiency in thyroid hormone leads to decrease in erythropoiesis due to slowing of metabolic rate, decrease in oxygen requirement, and decrease in erythropoietin levels.
 - Small percentage of hypothyroid patients (2% to 15%) have microcytic anemia.
 - Little significant effects on white blood cells and platelets occur.
- Myxedematous endemic cretinism:
 - Occurs in areas of endemic goiter and severe iodine deficiency
 - Represents most serious complication of endemic goiter
- In severe endemic goiter, irreversible abnormalities of intellect and physical development occur in a high number of patients.
- Clinically includes:
 - Mental deficiency with defects in hearing and speech
 - Disorders of standing and gait
 - Hypothyroidism and stunted growth
- Iodine deficiency is fundamental in cause of endemic cretinism and if severe enough, may be the only factor causing cretinism.
 - Other factors may include natural-occurring goitrogens, thyroid autoimmunity, trace element deficiency (selenium, manganese), congenital infections and perinatal anoxia.
- No specific therapy
- Rehabilitation is similar to patients with cerebral palsy.
- Prevention is by efficient iodine prophylaxis.
- Treatment of hypothyroidism
 - May be as simple as replacing thyroxine (T_4) using levothyroxine (LT_4)
 - Considered preferred treatment for hypothyroidism
 - Most patients treated with LT_4 as single agent
 - In some instances, hypothyroidism does not result from destruction of gland but due to another cause (Box 27-4) not be remedied by levothyroxine (LT_4) replacement.
 - In these instances, identification and treatment of underlying cause is paramount in controlling effects of hypothyroidism.

Thyrotoxicosis and Hyperthyroidism

Definitions:

Thyrotoxicosis: Clinical syndrome of hypermetabolism and hyperactivity that results when serum concentrations of free thyroxine (T_4), free triiodothyronine (T_3), or both are elevated.

Hyperthyroidism: Sustained increases in thyroid hormone biosynthesis and secretion by thyroid gland.

- Hyperthyroidism and thyrotoxicosis are not synonymous:

- Although many patients with thyrotoxicosis have hyperthyroidism, others do not, such as those patients in whom thyrotoxicosis is caused by release of excess hormone from thyroid in absence of increased synthesis, such as thyroiditis or exogenous thyroid hormone administration.

Clinical

- Hyperthyroidism less common than hypothyroidism
- Causes of thyrotoxicosis (with and without hyperthyroidism) listed in Box 27-5.

BOX 27-5 Causes of Thyrotoxicosis**Associated with Hyperthyroidism (Elevated Thyroid RAIU)**

- Graves disease
- Toxic nodular or multinodular goiter
- Solitary hyperfunctioning (toxic) adenoma
- Inappropriate TSH hypersecretion
- Gestational trophoblastic disease (hydatidiform mole; choriocarcinoma)
- Hyperemesis gravidarum
- Familial gestational hyperthyroidism

Associated with Low Thyroid RAIU

- Postpartum and sporadic silent thyroiditis
- Painful subacute thyroiditis (de Quervain, granulomatous)
- Acute infectious thyroiditis (bacterial, fungal, others)
- High-dose radiotherapy
- Surgical manipulation
- Infarction of adenoma
- Excess exogenous thyroid hormone
- Metastatic thyroid cancer
- Iodine-induced hyperthyroidism
- Struma ovarii

RAIU, Radioactive iodine uptake.

- Most common cause of spontaneous thyrotoxicosis is Graves disease, ranging from 60% to 90% in different regions of the world; most of remaining cases caused by:
 - Toxic nodular goiter
 - Autonomously functioning solitary thyroid adenoma
 - Several types of thyroiditis
- Clinical manifestations independent of cause:
 - Many patients with thyrotoxicosis have overt clinical and biochemical disease.
 - Thyrotoxicosis may be subclinical (subclinical thyrotoxicosis) defined as:
 - Normal serum free T_4 and T_3 concentrations and low serum thyrotropin (TSH) concentrations
 - Patients usually have no symptoms and signs of thyrotoxicosis but if present are usually mild and nonspecific.
- Biochemical confirmation of thyrotoxicosis can be determined on basis of:
 - Elevated levels of serum total and free thyroxine (T_4) and triiodothyronine (T_3) concentrations and decreased serum thyroid-stimulating hormone (TSH) levels
 - Biochemical confirmation of thyrotoxicosis does not include cause of disease.
- Factors that may determine manifestations of thyrotoxicosis include:
 - Age of patient:
 - Compared to younger patients, older patients have:
 - Fewer symptoms and signs of sympathetic activation (e.g., anxiety, hyperactivity, tremor)
 - More symptoms and signs of cardiovascular dysfunction (e.g., congestive heart failure, atrial fibrillation) and more likely to lose weight
 - Elderly patients with thyrotoxicosis may present with predominant involvement of one organ system and without the classic signs and symptoms of thyrotoxicosis referred to as apathetic thyrotoxicosis.
 - Presence or absence of a concomitant disease
- Clinical signs and symptoms of thyrotoxicosis include:
 - Nervousness, fatigue, weakness, heat intolerance, increased perspiration, hyperactivity, tachycardia, arrhythmias, palpitation, systolic hypertension, increased appetite, loss of weight, warm and moist skin, hyperreflexia, tremor, muscle weakness, and menstrual disturbances
- Signs associated with specific causes of thyrotoxicosis include:
 - Thyroid pain and tenderness with presence of a goiter (diffuse or nodular)
 - Ophthalmopathy and localized myxedema seen in Graves disease
- Laboratory findings:
 - Elevated serum total and free thyroxine (T_4) and triiodothyronine (T_3) concentrations
 - Most patients have high serum concentrations of both hormones.
 - Some patients have isolated increases in either thyroxine (T_4) or triiodothyronine (T_3).
 - Although serum thyroid hormone measurements are useful for detecting and monitoring thyrotoxicosis there are limitations:
 - There are other causes of elevated thyroxine (T_4) and triiodothyronine (T_3) concentrations (Box 27-6).
 - Some thyrotoxic patients have serum thyroxine (T_4) and triiodothyronine (T_3) concentrations within upper portion of normal range.
 - Other tests include measurement of thyroid radiiodine uptake (RAIU) and scan, thyroid ultrasound, and measurements of thyroid peroxidase, thyroglobulin, and TSH receptor (TSHR) antibodies.
 - RAIU most useful because it distinguishes between thyrotoxicosis caused by hyperthyroidism (elevated RAIU) and thyrotoxicosis caused by thyroiditis, exogenous thyroid hormone administration, and other etiologies (low RAIU)
- Significant systemic manifestations of thyrotoxicosis include:

BOX 27-6 Causes of Elevated Serum Thyroxine Concentrations

- Thyrotoxicosis
- Increased serum protein binding
- Increased serum thyroxine-binding globulin concentration:
 - Inherited
 - Estrogen (pregnancy, exogenous, tumoral production)
 - Hepatitis
 - HIV infection
 - Drugs (methadone, heroin, clofibrate, 5-fluorouracil)
- Familial dysalbuminemic hyperthyroxinemia
- Increased serum transthyretin binding and concentrations
 - Inherited
 - Pancreatic carcinoma, hepatoma
- Psychiatric and medical illness
- Drugs
 - Propranolol
 - Amiodarone
 - Radiographic contrast agents used for cholecystography
- Anti-T₄ immunoglobulins

- Cardiovascular:
 - Heart is major target organ for thyroid hormone action
 - Among many clinical manifestations of thyrotoxicosis, cardiovascular complications have highest potential for life-threatening consequences:
 - Increase in cardiovascular deaths demonstrated in patients with thyrotoxicosis
- Hemodynamic changes:
 - Increased systolic (increased stroke volume and rapid heart rate) and diastolic (shortened circulation time and decreased cardiac indices) functions
 - Despite presence of increased cardiac contractility and high output state caused by thyrotoxicosis, cardiac failure may (paradoxically) occur with decreased cardiac function, resulting in evidence of congestive heart failure, including pitting edema and pulmonary congestion.
 - Electrocardiographic changes include sinus tachycardia, atrial fibrillation
 - Increased metabolic demand may lead to:
 - Increased cardiac oxygen demand and risk of ischemia
 - Increased risk of atrial arrhythmias particularly fibrillation
 - Promotes development of congestive heart failure in susceptible individuals
 - Mitral valve prolapse is common abnormality found in Graves disease (pathophysiologic mechanisms for mitral valve prolapse in Graves disease are not known).
- Exertional dyspnea even without evidence of heart failure
- Muscular:
 - Generalized myopathy (weakness) and atrophy:
 - Most commonly involves pelvic girdle and shoulder muscles
 - Exophthalmic ophthalmoplegia (localized paralysis of ocular muscles) characterized by lid lag, lid retraction, and exophthalmos
 - Myasthenia gravis:
 - Coexistence of myasthenia gravis and thyrotoxicosis is uncommon (<1% of patients).
 - Incidence of thyrotoxicosis as a complication of myasthenia gravis is not as uncommon, occurring in up to 6% of myasthenia gravis patients.
 - Thyrotoxic periodic paralysis:
 - Characterized by attacks of flaccid paralysis (all extremities and trunk) with areflexia and abolition of electrical excitability may be a rare complication of thyrotoxicosis
 - Result of intracellular shift of potassium in genetically and clinically susceptible patient
- Neurologic (CNS):
 - Neuropsychiatric disorders:
 - Nervousness, irritability, tremulousness, anxiety disorders, depression, mania, and schizophreniform disorders may occur.
 - Discrete neurologic syndromes:
 - Chorea (rapid, nonrepetitive, random movement of extremities or less commonly facial muscle or trunk) is an unusual manifestation of thyrotoxicosis.
 - Resolves following successful treatment of thyroid condition
 - Severe acute systemic states with delirium, coma, and convulsions (thyrotoxicosis storm)
- Treatment of thyrotoxicosis:
 - Directed at cause of hyperthyroid state
 - Emphasis of treatment is on Graves disease because it is most common cause of thyrotoxicosis.
 - However, an underlying cause may not be readily established, rendering control of disease difficult.
 - Potential treatment modalities include:
 - Antithyroid drugs in an attempt to make the patient euthyroid: thionamides (e.g., propylthiouracil, methimazole); iodide; potassium perchlorate; lithium
 - Radioactive iodine
 - Surgery:
 - Subtotal thyroidectomy oldest form of therapy for thyrotoxicosis:

- Defined as removal of most of thyroid gland leaving few grams of posterior portion of each lobe
 - Presently performed in United States only under special circumstances:
 - In children, adolescents and pregnant women who are allergic to or noncompliant with antithyroid drugs
 - In patients with large goiters or severe ophthalmopathy
 - In patients who prefer destructive therapy
 - Many surgeons recommend total or near total thyroidectomy rather than subtotal thyroidectomy because of possibility of recurrent thyrotoxicosis due to thyroid regrowth with subtotal removal.
- Prognosis dependent on cause of the thyrotoxicosis (Box 27-5)
- Thyrotoxic storm or crisis:
 - Relatively rare but represents life-threatening syndrome characterized by exaggerated manifestations of thyrotoxicosis
 - Cardinal manifestations of thyrotoxicosis storm include:
 - Fever: usually $>102^{\circ}\text{F}$ (38.9°C)
 - Tachycardia: out of proportion to fever
 - Gastrointestinal dysfunction: nausea, vomiting, diarrhea, and, in severe cases, jaundice
 - CNS related: marked hyperirritability, anxiety, confusion, apathy, and, in extreme cases, coma
 - Above features in patient with a goiter, Graves disease ophthalmopathy, or a history of partially treated thyrotoxicosis may signal diagnosis of thyrotoxic storm.
 - Causes of thyrotoxicosis storm are:
 - Infection (most common), trauma (including vigorous palpation of the thyroid), surgery, hypoglycemia, stress, cessation of antithyroid drug medication, ^{131}I therapy, diabetic ketoacidosis, cerebrovascular accident, pulmonary ketoacidosis, iodinated contrast dyes
 - Precise mechanism of thyrotoxicosis storm is not fully known and it probably is multifactorial.
 - Laboratory findings:
 - Elevated serum total T_4 and T_3 , T_3 -resin uptake, and 24-hour radioiodine uptake
 - These levels are raised above normal but are not substantially different from those levels in uncomplicated cases of thyrotoxicosis.
 - Owing to potential high mortality, often necessary to initiate treatment without waiting for biochemical confirmation
 - Therapy:
 - Antithyroid drug directed against thyroid gland to decrease thyroidal production and secretion of T_4 and T_3

- Directed against systemic disturbances:
 - Treatment of fever
 - Correction of volume depletion and poor nutrition
 - Supportive therapy
- Amelioration of peripheral actions of thyroid hormone
 - Administration of β -adrenergic antagonist drug
- Treatment of any precipitating or underlying illness

NONAUTOIMMUNE THYROIDITIDES

Acute (Infectious) Thyroiditis (Figs. 27-34 and 27-35)

Definition: Presence of an inflammatory cell infiltrate dominated by polymorphonuclear leukocytes within thyroid gland.

Synonyms: Acute suppurative thyroiditis; infectious thyroiditis; pyogenic thyroiditis

Clinical

- Rare disease
- No gender predilection; may occur in all age groups
- Most often represents an infectious disease but may occur following exposure to radiation
- Tends to develop in immunocompromised and/or malnourished patients, including:
 - Patients with HIV or AIDS
 - Organ transplant patients on pharmacologic immunosuppression

Fig. 27-34. Acute thyroiditis.

Left, Acute thyroiditis characterized by the presence of polymorphonuclear leukocytes in the thyroid. *Right*, Filamentous gram-positive organisms consistent with *Nocardia* species were present.

Fig. 27-35. Actinomycotic thyroiditis.

Actinomycotic thyroiditis characterized by the presence of “sulfur” granules typical of *Actinomyces* microorganisms.

- Cancer patients undergoing chemotherapy
- Patients on immunomodulation therapy for other disorders
- Clinical presentation includes:
 - Fever with swelling and pain in neck region that may radiate or be referred to jaw and ear region
 - Additional signs and symptoms may include fatigue, dyspnea, dysphagia, and hoarseness.
 - Not infrequently there is an antecedent or concomitant history of upper aerodigestive tract infection.
 - Not infrequently, associated with concomitant localized infections or as part of a systemic process (i.e., sepsis)
- Thyroid gland is warm to hot on palpation.
- Patients are usually euthyroid, but hyperthyroidism and hypothyroidism may occur.
- Etiologic agents may include:
 - Bacteria, fungi, viruses, and parasites:
 - Causative bacteria include *Streptococcus pyogenes*, *Staphylococcus aureus*, *Pneumococcus*, and less commonly gram-negative bacteria:
 - In adults approximately 80% caused by *Streptococcus haemolyticus*, *Staphylococcus aureus* representing sole pathogen in approximately 70% of cases
 - In pediatric ages approximately 70% caused by alpha and beta-hemolytic *Streptococcus*
 - Causative fungus primarily reported to be *Aspergillus* species:
 - Virtually all affected patients are immunocompromised.
 - Other fungi causing thyroiditis include:
 - *Coccidioides immitis*, *Histoplasma capsulatum*, *Candida albicans*, *Allescheria boydii*, *Nocardia asteroides*

- Causative viruses include cytomegalovirus (in patients with AIDS).
- Other infectious agents may include *Pneumocystis jiroveci* (in patients with AIDS), mycobacteria, and *Actinomyces*.

- Spread of infection to thyroid gland via lymphatics and, less commonly, via hematogenous spread
- Cultures for microorganisms may be of assistance in diagnosis:
 - Microbiologic analysis can be performed on material from fine-needle aspiration.

Pathology

Fine-Needle Aspiration Biopsy

- Polymorphonuclear leukocytes are present.
- Microorganisms can be identified by histochemical analysis.

Gross

- Variable appearance including focal or diffuse enlargement; in some instances, thyroid appears normal
 - Abscess formation as seen by soft purulent areas may be identified.

Histology

- Pathologic process may be suppurative or nonsuppurative.
- Focal to diffuse acute inflammatory cell infiltrate (polymorphonuclear leukocytes) with destruction of follicular epithelial cells
- Areas of abscess formation characterized by dense pool of leukocytes can be seen.
- Areas of necrosis and leukocytic debris can be seen.
- Depending on causative microorganism, offending agent may or may not be identifiable by light microscopy.
- Histochemistry:
 - Histochemical stains (e.g., Gram stain, GMS, PAS, others) may assist in identification of the microorganism.
- Immunohistochemistry or in situ hybridization:
 - May assist, in particular, in viral disease:
 - Cytomegalovirus
 - Herpes simplex virus
- In a severely immunocompromised patient, typical granulomatous inflammatory process may not occur in the face of mycobacterial or fungal infection; instead, changes of acute thyroiditis may be seen.

Treatment and Prognosis

- Treatment predicated on diagnosis and identification of the causative microbe
 - Once identified, appropriate antimicrobial therapy initiated

BOX 27-7 Granulomatous Lesions of the Thyroid Gland

- Infections (mycobacterial and fungal)
 - Sarcoidosis
 - Subacute thyroiditis (including silent thyroiditis)
 - Multifocal granulomatous thyroiditis (palpation thyroiditis)
 - Postoperative necrotizing granulomas
 - Others
-
- Surgical intervention (drainage) may be required in presence of abscess formation.
 - Prognosis especially for bacterial-related acute thyroiditis is excellent with most patients experiencing recovery; rarely, recurrence and even death may occur.
 - Recurrent acute suppurative thyroiditis may occur secondary to a piriform sinus fistula:
 - Usually left-sided
 - Identified by radiographic evaluation
 - Treatment includes fistulectomy

Granulomatous Thyroiditis

Definition: Presence of well-formed granulomas in the thyroid gland.

- More common causes of granulomas in thyroid gland are listed in [Box 27-7](#).

Infectious Granulomatous Thyroiditis (Fig. 27-36)

Definition: Infectious thyroiditis caused by an identifiable microorganism that may (or may not) result in granulomatous inflammation.

Synonym: Acute mycotic thyroiditis

Clinical

- Granulomatous inflammation of thyroid gland caused by a microorganism is extremely uncommon.
- Causative microorganisms include mycobacteriae and fungi.
- Typical clinical setting for this occurrence is an immunosuppressed or immunocompromised patient.
- Rarely reported to be associated with silicone breast implants
- Clinical presentation may be similar to that of acute thyroiditis and may include:
 - Fever with swelling and pain in the neck region radiating or referred to the jaw and ear region
- Thyroid glands are warm to hot on palpation.
- Patients are usually euthyroid but both hyperthyroidism and hypothyroidism may occur.
- Etiologic agents may include various fungi and mycobacteriae.

Fig. 27-36. Infectious granulomatous thyroiditis.

Caseating granulomas are seen showing central necrosis surrounded by a histiocytic cell reaction including multinucleated giant cells. Although histochemical staining (AFB, GMS) for microorganisms was negative, the patient proved to have *M. tuberculosis* as determined by molecular testing (i.e., polymerase chain reaction).

- Mycobacterial infection of thyroid is rare even in patients with miliary tuberculosis.
- Cultures for microorganisms may be of assistance in the diagnosis; microbiologic analysis can be performed on material from fine-needle aspiration.

Pathology**Gross**

- Variable but may include soft purulent (caseating) areas, abscess formation, or miliary tubercles

Histology

- Classic caseating granulomas may be present in either mycobacterial or fungal infection and include:
 - Foci of central necrosis surrounded by a histiocytic cell reaction with scattered associated multinucleated giant cells
 - Irrespective of causative organism, histologic picture of mycobacterial infection remains similar
- In immunocompromised patients, typical granulomatous inflammatory process may not occur in the face of mycobacterial or fungal infection; rather, changes of acute thyroiditis are seen:
 - Focal to diffuse acute inflammatory cell infiltrate (polymorphonuclear leukocytes) with destruction of follicular epithelial cell architecture
 - Areas of abscess formation characterized by dense pool of leukocytes can be seen.
 - Areas of necrosis and leukocytic debris may be present.
- Depending on causative microorganism, the offending agent may or may not be identifiable by light microscopy.

- Special stains/testing:
 - Histochemical stains may assist in the identification of the microorganism:
 - Fungal infection:
 - Gomori methenamine silver (GMS), periodic acid-Schiff (PAS), mucin stains
 - Mycobacterial infection:
 - Acid-fast bacilli (AFB) and Ziehl-Neelsen
 - ◻ Special stains based on capability of forming stable mycolate complexes with certain aryl methane dyes referred to as “acid-fastness”; depending on the stain, the organisms when identified appear beaded, showing a red or purple color; organisms are often extremely difficult to identify and may defy detection despite all efforts
 - Immunohistochemistry:
 - Positive immunoreactivity with monoclonal antibody to *Mycobacterium tuberculosis* complex
 - Polymerase chain reaction (PCR)
 - Can be used for identification of *Mycobacterium tuberculosis*

Differential Diagnosis

- Sarcoidosis
- Mycotic infections
- Noninfectious granulomatous processes:
 - de Quervain thyroiditis
 - Palpation thyroiditis
 - Postoperative necrotizing granulomas:
 - Similar in appearance to those occurring in prostate and bladder

Treatment and Prognosis

- Predicated on diagnosis and identification of the causative microbe
 - Once identified, appropriate antimicrobial therapy is initiated.
- Surgical intervention (drainage) may be required in presence of abscess formation.
- Prognosis for fungal infection of the thyroid is poor:
 - Generally is terminal event in immunocompromised patient
- Prognosis of mycobacterial infection of thyroid correlates with that of other organ system involvement.

Sarcoidosis of Thyroid Gland

(Figs. 27-37 and 27-38)

Definition: Multisystem chronic granulomatous disease of unknown cause that may involve the thyroid gland as part of systemic process, or, rarely, localized to thyroid gland.

Fig. 27-37. Sarcoidosis of the thyroid gland.

A, Intrathyroidal granulomatous inflammation characterized by the presence of well-formed granulomas with a histiocytic cell infiltrate and multinucleated giant cells without central necrotic material (caseation). **B**, Rarely necrosis may be present in association with sarcoid granulomas.

Clinical (Limited to Thyroid Involvement)

- Uncommon; when it occurs it is more often a part of systemic disease rather than isolated to thyroid gland
 - In this setting, patient generally does not present with symptomatic thyroid disease, but pathologic identification of thyroid involvement is at autopsy.
- Isolated sarcoidosis of thyroid gland is rare.
- No gender predilection; occurs in all age groups but most commonly seen in young adults
- Clinical presentation in symptomatic thyroid disease includes neck or thyroid mass, appearing as a hypo-functioning “cold” nodule on thyroid scanning.
- Clinical presentation as part of systemic disease includes fever, weight loss, and hilar adenopathy.
- No laboratory findings specific for or diagnostic of sarcoidosis:
 - Cutaneous anergy to skin test antigens may be seen (Kveim test).

Fig. 27-38. Sarcoidosis of the thyroid gland.

Findings in the cytoplasm of the giant cells in (thyroid) sarcoidosis that may assist in the diagnosis include (**A** and **B, left**): star-shaped structures referred to as asteroid bodies; (**B, right**) calcific laminated bodies called Schaumann bodies.

- Angiotensin-converting enzyme (ACE) levels elevated in association with sarcoidosis:
 - ACE levels directly related to number of organs affected
 - Mature granulomas tend to produce less ACE levels than developing new granulomas.
 - Correlation between disease activity and ACE levels:
 - As disease progresses to fibrosis, ACE levels decline.
 - ACE levels increased in other granulomatous diseases, although not as frequently as in sarcoidosis; frequency of elevation in other granulomatous disorders is 10%.
 - ACE levels increased in other nongranulomatous disorders (e.g., multiple sclerosis, Addison disease, hyperthyroidism, diabetes mellitus, others).
 - Given above, ACE not considered a diagnostic test for sarcoidosis

- Diagnosis generally one of exclusion and made by correlation of clinical, radiologic, and pathologic findings
- May rarely occur in association with papillary thyroid carcinoma and Graves disease

Pathology

Histology

- Noncaseating granulomas consisting of epithelioid histiocytes surrounded by a mixed inflammatory infiltrate and multinucleated (Langhans type) giant cells
- Intracytoplasmic inclusions may be identified, including:
 - Star-shaped referred to as asteroid bodies
 - Calcific laminated bodies referred to as Schaumann bodies
- Intervening thyroid gland essentially unremarkable
- All special stains for microorganisms (Brown and Hopps, Gomori methenamine silver [GMS], acid-fast bacilli, and Ziehl-Neelsen [for acid-fast organisms]) are negative.
- Immunohistochemistry:
 - Absence of thyroglobulin in granulomatous foci

Differential Diagnosis

- Mycobacterial infection
- Fungal infections

NOTE: Pathologic features of sarcoidosis are characteristic but they are not specific; therefore diagnosis of sarcoidosis can be considered only in the absence of identifying an infectious agent.

Treatment and Prognosis

- Those cases presenting with a symptomatic thyroid nodule may have surgical resection of the mass.
- Treatment for systemic sarcoidosis is with corticosteroid therapy.
- Prognosis for systemic disease is generally good, with up to 70% of patients improving or remaining stable following therapy.
- Advanced multisystem disease leading to extensive pulmonary involvement and respiratory failure may occur but is seen in only a small percentage of cases.

Subacute Thyroiditis (de Quervain Thyroiditis) (Fig. 27-39)

Definition: Granulomatous inflammatory condition of thyroid gland with characteristic clinical and pathologic findings.

Synonyms: Pseudogranulomatous or granulomatous thyroiditis; giant cell thyroiditis; acute simple thyroiditis; noninfectious thyroiditis; pseudotuberculous

Fig. 27-39. Subacute thyroiditis (de Quervain thyroiditis).

A, There is destruction of the follicular epithelial cells with colonization of the follicles by an inflammatory cell infiltrate that includes multinucleated giant cells. The gland has a lobular appearance with interlobular fibrosis. **B** and **C**, Destruction of the follicular epithelial cells, which are replaced by neutrophils and multinucleated giant cells. In **(B)** colloid is present and appears “floating” within the neutrophilic cell infiltrate; in **(C)** there is loss of colloid.

thyroiditis; migratory “creeping” thyroiditis; struma granulomatosa; thyroiditis acute simplex (as originally described by Mygind)

Clinical

- Less common than Graves disease and chronic lymphocytic (Hashimoto) thyroiditis representing <3% of all thyroid abnormalities
- Affects women more than men (3 to 6:1); most common in second to fifth decades of life:
 - Uncommon in children and in elderly patients
- Clinical presentation includes:
 - Neck pain that may be localized to the thyroid (one lobe or the entire gland) or may radiate to the jaw, ears, face, and chest
 - General (systemic) manifestations may include malaise, fatigue, fever, chills, weight loss, anorexia, and myalgia.
- On palpation, gland is enlarged, exquisitely tender, and firm to hard.
 - Enlargement usually diffuse but may be asymmetric with limited (unilateral) involvement:
 - Postviral painless form of subacute thyroiditis reported referred to as atypical subacute thyroiditis
 - Findings in these patients may include fever of unknown origin.
- Laboratory findings (change with stage of disease):
 - Early or hyperthyroid (thyrotoxic) phase:
 - Due to damage to thyroid follicular cells, hyperthyroid condition resulting from elevated serum levels of T_4 , T_3 , and thyroglobulin
 - Increased serum and urine iodine and decreased serum TSH levels
 - High levels of erythrocyte sedimentation rate and C reactive protein
 - Hypothyroid phase:
 - With progression of disease, hypothyroid state ensues due to destruction of a larger portion of the gland and absence of hormone production and iodine uptake (decreased serum levels of T_4 , T_3 , and thyroglobulin, and increased serum TSH level).
 - Low radioactive iodine uptake:
 - Most often <2% at 24 hours
 - Hypothyroid phase in most patients lasts about 1 to 2 months with an occasional patient remaining permanently hypothyroid.
- Etiology:
 - In all probability associated with infection with strong evidence supporting a viral agent:
 - Clinical presentation may be preceded by an upper respiratory tract infection that may have a prodromal phase characterized by muscle aches and pains, malaise, and fatigue.

- Concomitant elevation of white blood cell count is not present as would be expected in a bacterial-related disease.
- Most often identified in summer months coinciding with summer enterovirus infections
- Antibody studies (acute and convalescent phase serum) have shown circulating antibodies to various viruses, including mumps, measles, influenza, Epstein-Barr virus, coxsackievirus, adenovirus and echovirus.
- Autoimmunity may play a role in development of subacute thyroiditis:
 - Thyroid antibodies found in some patients with subacute thyroiditis
 - These antibodies are transiently present and disappear following resolution of disease.
 - Presence of antithyroid antibodies may represent a reaction to released antigens following follicular epithelial destruction rather than representative of true autoimmune condition
 - Reports link subacute thyroiditis with hepatitis vaccine, influenza vaccine, influenza A virus subtype H1N1 vaccine, during interferon and interleukin-2-therapy and combination interferon and ribavirin therapy
- Genetic association:
 - Association between subacute thyroiditis and HLA-Bw 35 supports a genetic predisposition to the development of this disease:
 - Relative risk of HLA-Bw in subacute thyroiditis ranges from 8.0 to 56.6.
 - Weak association with HLA-DRw8 reported in Japanese patients
 - Familial occurrence has been reported.
- Radiology
 - Radioisotopic scans in early stages of disease show patchy and irregular uptake or no uptake.
 - Ultrasound shows hypoechogenicity in involved areas.

Pathology

Fine-Needle Aspiration Biopsy

- In early stages of disease, acute inflammatory cells with microabscesses can be seen.
- With progression of disease, a mixed inflammatory infiltrate is seen including lymphocytes, histiocytes, plasma cells, multinucleated giant cells, and polymorphonuclear leukocytes.
- Degenerative changes of follicular epithelial cells are present.
- In presence of extensive fibrosis, aspirates may be acellular.

Gross

- On sectioning, thyroid gland is firm to hard, tan-white in appearance with one or more ill-defined

nodules varying in size from a few millimeters to several centimeters.

Histology

Histologic appearance varies with phase of disease:

- Early phase:
 - Destruction of follicular epithelial cells with extravasation and depletion of colloid
 - Colloid may be identifiable “floating” within inflammatory cell infiltrate.
 - Periodic acid-Schiff (PAS) staining is simple and effective stain for identifying colloid.
 - “Colonization” of thyroid follicles by an inflammatory infiltrate consists of polymorphonuclear leukocytes (including microabscesses) in initial stages followed by mature lymphocytes, histiocytes, and multinucleated giant cells.
 - Inflammatory cells may involve adjacent follicles.
- Later phase:
 - Polymorphonuclear leukocytes are replaced by chronic inflammatory infiltrate composed of lymphocytes, histiocytes, giant cells, and plasma cells.
 - Absence of follicular epithelial cells replaced by inflammatory cells
 - Fibrosis seen between follicles and between lobules
- Regenerative phase:
 - Follicular regeneration
 - Minimal residual irregular fibrosis variably present

Differential Diagnosis

- Multifocal granulomatous thyroiditis (palpation thyroiditis)
- Chronic lymphocytic (Hashimoto) thyroiditis
- Mycobacterial infection
- Sarcoidosis
- Neoplastic proliferation (not usually a histologic problem but on the basis of the clinical appearance this may fall within the differential diagnosis)

Treatment and Prognosis

- Self-limited clinical course:
 - Acute phase lasts from 3 to 6 weeks but may last up to 4 months.
- Most effective therapy in more severe cases includes corticosteroids (oral prednisone).
 - Provide dramatic relief of pain and swelling within a few hours of administration:
 - In most cases within 24 to 48 hours
 - Administered for a week followed by tapering over at least 4 to 6 weeks

- Despite clinical response underlying inflammation may persist and symptoms recur if steroids tapered too quickly.
- Symptoms may recur in approximately one third of patients on reduction or cessation of steroid therapy.
 - In these patients readministration of steroids will resolve symptoms and ultimately patients will experience full recovery.
- Salicylates and other nonsteroidal anti-inflammatory medications have been used with good results:
 - Often adequate to decrease pain in mild to moderate cases
- Although surgical intervention is not primary treatment, when resection is performed it can be done safely and with low associated morbidity.
 - Patients with atypical features and patients with euthyroidism are more likely candidates than others for surgical intervention.
- Prognosis is excellent with complete resolution of disease.
 - Permanent hypothyroidism is rare but may occur in 5% to 15% of patients.
- Approximately 50% of hypothyroid patients are symptomatic; however, supplemental T₄ therapy is not required.
- Etiology is uncertain:
 - Viral cause sought but not confirmed
 - Autoimmunity also considered but not confirmed
- Thyroid enlargement occurs in up to 60% of patients:
 - Enlargement may be asymmetric, in which patients have a dominant, firm mass confined to one thyroid lobe.
 - Pain and tenderness is rare and when present is mild.
- Histologic changes:
 - Diffuse or focal lymphocytic thyroiditis
 - Follicular destruction present
 - Oncocytic cytoplasmic change of follicular epithelial cells uncommon but may be focally present
 - Absence of fibrosis
- Differential diagnosis:
 - Postpartum thyroiditis:
 - Similar clinical and histologic feature as painless (silent) subacute thyroiditis
 - Antecedent history of pregnancy
 - Chronic thyroiditis
 - Absence of extensive follicular destruction
- Disease course is similar to that of subacute thyroiditis:
 - Often self-limiting not requiring treatment
 - Adrenergic beta-blockers may be used in hyperthyroid phase
 - Temporary thyroxine replacement in hypothyroid phase
 - 50% of patients return to euthyroid phase
 - Permanent hypothyroidism may develop years later.

Painless (“Silent”) Subacute Thyroiditis

Definition: Form of hyperthyroidism characterized by painless nontender thyroid gland, increased levels of T₄ and T₃, low radioactive iodine uptake, and spontaneously resolving hyperthyroidism.

Synonyms: Atypical subacute thyroiditis; transient hyperthyroidism with lymphocytic thyroiditis

Clinical

- Incidence not known but estimated to be as high as 20% to 30% of all cases of subacute thyroiditis
- Affects women more than men; most common in the third to sixth decades of life but may occur in all age ranges
- Onset and severity of disease is variable:
 - Initial phase includes mild to moderate thyrotoxicosis lasting 1 to 2 months (transient thyrotoxicosis) with reduced radioactive iodine uptake followed by euthyroidism of several weeks duration, which in turn, is followed by hypothyroid phase of several months.
- Clinical presentation of thyrotoxicosis phase is usual one but, in addition, may include some of its unusual manifestations such as:
 - Atrial fibrillation, diffuse myalgia, periodic paralysis, and lid lag and lid retraction
 - Exophthalmos, localized myxedema, and thyroid acropathy do not occur.

Multifocal Granulomatous Thyroiditis (Palpation Thyroiditis) (Fig. 27-40)

Synonym: Martial arts thyroiditis

- Iatrogenetically induced lesions caused by vigorous (traumatic) palpation of thyroid gland:
 - Focal lesion or multifocal lesions due to manipulation of thyroid gland during physical examination with rupture of thyroid follicles and extrusion of colloid in affected area
- No specific demographics or clinical parameters associated with palpation thyroiditis
- Does not cause abnormalities in thyroid function (hypothyroidism or hyperthyroidism)
- Incidental microscopic finding in thyroid glands resected for other reasons

Fig. 27-40. Palpatation thyroiditis.

Palpatation thyroiditis may be a focal or multifocal process in which the thyroid follicular epithelial cells are replaced by histiocytes and multinucleated giant cells.

- Histology:
 - Isolated follicle or groups of follicles show loss of follicular epithelial cells and replacement by a mixed chronic inflammatory cell infiltrate predominantly comprised of histiocytes, as well as lymphocytes and plasma cells; multinucleated (foreign body giant reaction) may be present.
 - Additional histologic changes may include hemorrhage, hemosiderin deposition, and hemosiderin-laden macrophages.
 - Presence of colloid varies:
 - In some cases residual colloid is present and in others it is absent.
 - PAS stain may be of assistance in identifying residual colloid.
 - Necrosis is generally not found but occasionally may be present.
- Differential diagnosis
 - C-cell hyperplasia: differentiation assisted by immunohistochemistry:
 - Palpatation thyroiditis: CD68 (KP1) and lysozyme positive, calcitonin, synaptophysin and chromogranin negative
 - C-cell hyperplasia: calcitonin, synaptophysin, and chromogranin positive, thyroglobulin negative
 - Subacute (de Quervain) thyroiditis:
 - Focality of palpatation thyroiditis with involvement of one to several follicles and associated histologic findings including absence of acute inflammatory cells allow distinguishing palpatation thyroiditis from subacute thyroiditis.
 - Sarcoidosis or infectious granulomatous thyroiditis:
 - In sarcoidosis, granulomas are interstitially located.

– In infectious granulomatous there is usually necrosis, which is not present in palpatation thyroiditis.

- No specific treatment required:
 - Self-limiting; in all probability, there is spontaneous regression of histologic changes
- Not associated with any untoward sequelae

Invasive Fibrous Thyroiditis (Riedel Disease) (Figs. 27-41 through 27-45)

Definition: Fibrosclerosing process of thyroid gland and adjacent soft tissues of neck felt to belong to spectrum of IgG4-related diseases.

Synonyms: Riedel struma; ligneous thyroiditis

Clinical

- Rare disease with reported prevalence of 0.06 to 0.3%
- Affects women more than men; primarily occurs in adults
- Clinical presentation includes:
 - Painless neck mass and/or goiter
 - Pressure in the anterior neck often associated with dysphagia, dyspnea, stridor, tracheal narrowing
 - Rarely, vocal cord paralysis may occur.
- Thyroid enlargement described as woody or stony hard on palpation and adherent or fixed to surrounding structures in the neck:
 - Involvement of thyroid gland may be limited in extent so that one side is predominantly involved but bilateral and complete involvement of thyroid can also occur.
 - Presence of a hard and fixed thyroid mass clinically simulates a neoplastic lesion (i.e., carcinoma).
 - Impression of neoplasm further suspected in cases associated with cervical lymph node involvement
- Laboratory findings:
 - Hypothyroidism occurs in 30% to 40% of patients and is permanent.
 - Hypoparathyroidism may also occur.
 - Serum levels of IgG4 may or may not be elevated.
 - Circulating antithyroid antibodies are usually absent but may be present in small amounts:
 - Presence of antithyroid antibodies may represent a reaction to released antigens following follicular epithelial destruction (similar to subacute thyroiditis) rather than representative of an autoimmune condition.
- Disease process may be localized to thyroid gland and perithyroidal tissues or may be part of a systemic fibrosing disease.

Fig. 27-41. Invasive fibrous thyroiditis (Riedel disease).

A, Axial, contrast-enhanced CT scan shows an enlarged, very-low-attenuation nonenhancing thyroid gland. The fat plane in the upper tracheoesophageal groove is obliterated bilaterally. This patient had Riedel struma (thyroiditis).

B, Axial T1-weighted MR image on a different patient than in part A shows similar findings of a diffusely enlarged gland and infiltration of the tracheoesophageal fat plane bilaterally. This patient had Riedel thyroiditis. This is virtually the only benign thyroid disease that can cause a recurrent laryngeal nerve paralysis. (From Som and Curtin: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Figs. 41-38 and 41-39, page 2632.)

- Extracervical fibrosclerosis may include:
 - Retroperitoneum, mediastinum, orbital, pancreas, hepatobiliary, lung, sinonasal tract, salivary glands (parotid, submandibular)
- Thyroid involvement may coexist with one of above sites of involvement.
- Evidence supports Riedel thyroiditis being a part of spectrum of IgG4-related diseases:
 - Based on association with extracervical fibrosclerosing lesions, histologic features, immunohistochemical findings, and response to treatment (see below)

Fig. 27-42. Invasive fibrous thyroiditis (Riedel disease) resection specimen.

There is complete replacement of any identifiable tan-brown thyroid tissue by dense, firm to hard tan-white fibrous tissue.

Pathology

Fine-Needle Aspiration Biopsy

- Typically, aspiration generates a scanty amount of cellular material referred to as dry tap.

Gross

- Replacement of thyroid by dense tan-white, firm to hard tissue

Histology

- Destruction and replacement of thyroid parenchyma by dense collagen (keloid-like bands of fibrosis):
 - Fibrosing process not confined to thyroid but also involves extrathyroidal connective tissue structures such as skeletal muscle, adipose tissue, nerves, and vascular spaces
 - Parathyroid glands can also be involved.
- In addition to fibrosis, there is chronic inflammatory cell infiltrate that is:
 - Predominantly composed of mature plasma cells and lymphocytes
 - Eosinophils may be present.
 - Giant cells are not present.
- Vasculitis primarily involving veins (phlebitis) characterized by adventitial inflammation that may “invade” through the full thickness of vessel wall with thrombotic effect:
 - May be readily apparent or may be difficult to identify
 - May not be present in all cases
- Remnant of thyroid follicles may be present (but may be difficult to identify), situated within the dense collagen, showing limited to atrophic changes.

Fig. 27-43. Invasive fibrous thyroiditis (Riedel disease).

A, The thyroid gland parenchyma is completely effaced and replaced by dense keloid-like bands of fibrous tissue with an associated chronic inflammatory cell infiltrate. **B**, Residual colloid-filled thyroid follicles (*arrowheads*) can be seen but most of the thyroid has been replaced by keloid-like fibrosis and chronic inflammatory cells. **C** and **D**, Residual thyroid follicles (*arrowheads*) with and without associated colloid are identified in association with a variable degree of fibrosis and density of mature plasma cell infiltrate. Immunostaining (not shown) included the presence of abundant IgG4+ plasma cells with an increase in the IgG4/IgG ratio.

- Overall histopathologic findings not associated with:
 - Oncocytic metaplasia of follicular epithelial cells as seen in advanced lymphocytic thyroiditis
 - Granulomatous inflammation
- In some cases, preexisting or coexisting lesions may be present such as adenomatoid nodule(s), follicular adenoma, follicular carcinoma, and papillary thyroid carcinoma.
- Histochemistry:
 - Elastic stains may assist in identifying presence of vasculitis.
 - PAS stain may assist in identifying colloid in thyroid follicles.
- Immunohistochemistry:
 - Immunostaining for IgG4 and IgG show:
 - Presence of abundant IgG4+ plasma cells
 - Increase IgG4/IgG ratio
 - Plasma cells:
 - CD138, CD79a positive
 - Kappa and lambda light chain staining:
 - Predominance of expression of lambda chains and IgA reported
 - Thyroid follicular epithelium:
 - Thyroglobulin and TTF1 reactive:
 - Can be used to assist in identification of thyroid follicular epithelium
 - D2-40 staining reported to show increased number of lymphatic vessels:
 - Suggest participation of lymphatic vessels in pathogenesis

Fig. 27-44. Invasive fibrous thyroiditis (Riedel disease).

Vasculitis in invasive fibrous thyroiditis (Riedel disease) primarily involving veins (phlebitis) characterized by (A) adventitial inflammation that may (B) “invade” through the full thickness of vessel wall with thrombotic effect. The inflammatory cells are composed of mature plasma cells and lymphocytes. In both images elastic stain shows disruption with focal discontinuation of the black staining elastic membranes by the inflammatory cell infiltrate that is present throughout the wall of the vascular spaces.

Differential Diagnosis

- Chronic lymphocytic (Hashimoto) thyroiditis, fibrosing variant:
 - See later in this chapter.
 - Suggestion that fibrosing variant of chronic lymphocytic (Hashimoto) thyroiditis also part of spectrum of IgG4-related diseases but not unequivocally confirmed
 - Rare reported instances of combined Riedel disease and chronic lymphocytic (Hashimoto) thyroiditis:

Fig. 27-45. Invasive fibrous thyroiditis (Riedel disease).

The fibrous and mixed chronic inflammatory infiltrate may involve extrathyroidal structures such as the soft tissue of the neck, including (A) mature adipose tissue, (B) parathyroid glands (arrowheads) with angiocentric inflammation (center).

- Characterized by clinical and laboratory findings of Hashimoto disease and pathologic findings of Riedel disease
- Likely a coincidental occurrence
- Findings in Riedel disease that allow for separation from fibrous variant of Hashimoto thyroiditis include:
 - Extension of pathologic (fibroinflammatory) process outside the thyroid gland:
 - Occurs in Riedel disease
 - Does not occur in (fibrous variant of) Hashimoto thyroiditis
 - Cytoplasmic oncocytic cell changes in follicular epithelial cells:
 - Absent in Riedel disease
 - Present in (fibrous variant of) Hashimoto thyroiditis

- Vasculitis/phlebitis:
 - Present in Riedel disease
 - Absent in (fibrous variant of) Hashimoto thyroiditis
- Plasma cells:
 - In Riedel disease express lambda chains and IgA
 - In fibrous variant of Hashimoto thyroiditis predominantly express kappa chains and IgG
- Subacute thyroiditis
- Carcinomas with extensive fibrosis
- Sclerosing lymphomas

Treatment and Prognosis

- Wide surgical resection has been traditional suggested treatment:
 - Uninvolved thyroid need not be resected
- Corticosteroid or rituximab appear to be efficacious treatment (supplanting surgical therapy) associated with:
 - Clinical and radiologic improvement:
 - Reduction in lesion size

- Serologic improvement:
 - Progressive decline in serum IgG4 concentrations
- Serum IgG4 concentrations may remain low and clinical disease activity may remain quiescent in a significant proportion of patients.

Radiation Thyroiditis

Definition: Morphologic alterations of thyroid gland due to external radiotherapy or radioiodine therapy resulting in functional thyroid abnormality (hypothyroidism).

Clinical

External Radiotherapy-Associated Thyroiditis (Fig. 27-46)

- External irradiation to neck used to treat patients with mucosal tumors (typically, squamous cell carcinomas) of the upper aerodigestive tract, metastatic tumors to neck (primarily those originating from

Fig. 27-46. Radiation associated histologic changes in the thyroid gland.

Histologic changes associated with radiation thyroiditis may include **(A)** nodular hyperplasia with irregular fibrosis; **(B)** parenchymal atrophy and sclerosis; **(C and D)** nuclear (endocrine) atypia, including nucleomegaly and hyperchromasia.

the upper aerodigestive tract) and malignant lymphomas:

- In past, external radiotherapy used in treatment of acne, enlarged tonsils and adenoids, thymic enlargement, benign cervical lymphadenopathy, pertussis, epilation, and benign tumors (hemangiomas)
- External radiotherapy-induced hypothyroidism may occur in 25% to 50% of patients so treated.
- Time interval from radiation treatment to development of hypothyroidism usually ranges from 2 to 7 years; however, hypothyroidism may develop within 1 year from time of radiation treatment.
- Effects (hypothyroidism) of external irradiation on thyroid gland is dose related:
 - Higher doses, higher frequencies of hypothyroidism
 - Significant linear radiation dose response for thyroid nodules, including benign nodules and malignant tumors, exists in atomic bomb survivors
 - No significant dose response for autoimmune thyroid diseases
- In most patients, hypothyroidism is subclinical but may be overt.
 - Patients with subclinical hypothyroidism may develop overt hypothyroidism later.
 - In other patients (subclinical) hypothyroidism is transient.
- Acute (weeks to months) effects of external irradiation (i.e., hypothyroidism) result in functional abnormalities (as determined by thyroid function testing) rather than causing any significant morphologic changes.
- Major effect of ionizing irradiation on thyroid tissue is impairment of the reproductive capacity of the follicular cells.

Radioiodine (Iodine-131 [¹³¹I])-Associated Thyroiditis

- ¹³¹I therapy is used in treatment of hyperthyroidism, especially for patients with Graves disease.
- Effects (hypothyroidism) of ¹³¹I on thyroid gland is less a function of dose and more correlated with time:
 - In fact, virtually all patients eventually become hypothyroid following ¹³¹I therapy even 10 years or more after therapy.
 - In patients who received ¹³¹I, overt hypothyroidism is usually preceded by subclinical hypothyroidism.

Pathology in Radiation Thyroiditis

Gross

- Externally irradiated thyroid glands are small and fibrotic.

Histology

- Most common abnormality is nodular hyperplasia.
- Morphologic changes that can be seen include:
 - Increased cellularity with severe cytologic atypia characterized by:
 - Markedly enlarged and bizarre-shaped nuclei (nucleomegaly) with hyperchromasia, prominent nucleoli, and nuclear crowding
 - Cytologic atypia is randomly found.
 - May be limited to one area
 - May be haphazardly found in several foci
 - Atypical nuclear features not specific and can be seen in nonirradiated thyroid glands
 - Papillary growth pattern
 - Follicular atrophy
 - Oxyphilic and/or squamous metaplasia
 - Decreased or absent colloid
- Additional changes may include:
 - Parenchymal fibrosis
 - Chronic (lymphocytic cell) inflammation
 - Vascular sclerosis and intimal thickening (endarteritis obliterans):
 - Vascular changes are fairly specific for irradiated tissues in general, including irradiated thyroid glands.
 - Inflammatory cell infiltrate cuffing vessels can be seen.
- Benign and malignant tumors may develop secondary to external irradiation, including:
 - Adenomatoid nodules and follicular adenomas:
 - May show atypical cytologic features including hypercellularity and markedly enlarged, hyperchromatic bizarre-appearing nuclei
 - Papillary thyroid carcinoma most common malignant neoplasm to develop
 - Follicular thyroid carcinoma may develop.
 - Rarely, undifferentiated (anaplastic) thyroid carcinoma occurs.

Differential Diagnosis

- Cellular adenomatoid nodules
- Dyshormonogenetic goiter
- Papillary carcinoma
- Follicular carcinoma

Treatment and Prognosis

- Hypothyroidism resulting from irradiation of thyroid gland treated by thyroid hormone therapy
- Prophylactic thyroidectomy in patients developing nodular hyperplasia following external irradiation can be considered.
- Complications of externally irradiated thyroid glands include development nodular hyperplasia and development of benign and malignant neoplasms.

- Papillary thyroid carcinoma is most common malignant tumor to occur following external irradiation:
 - May develop many years (decades) following the radiotherapy
 - Risk of developing postirradiation (papillary) carcinoma is small
 - All population ages are at risk of developing postirradiation thyroid cancers.
 - May be single focus or may be multifocal (within one lobe or throughout the entire gland)
 - Histology often that of usual or classic type of papillary thyroid carcinoma
- Papillary carcinomas developing following radiation exposure from nuclear fallout occur over shorter periods of time:
 - Post-Chernobyl radiation-induced papillary thyroid carcinomas
 - Develop over much shorter periods of time as compared with same tumor developing following external beam radiotherapy
 - Solid growth pattern (i.e., solid variant of papillary thyroid carcinoma) may predominate and is most common growth pattern identified, characterized by:
 - Solid nests may be separated by thin fibrovascular stroma, creating an “insular” growth.
 - Characteristic nuclear features
 - Typically lack marked pleomorphism, increased mitotic figures, and necrosis
 - Frequent *BRAF* mutation, *RET/PTC1* rearrangement, and low proliferation indices
 - Associated with higher frequency of lymph node metastases, higher frequency of angioinvasion, and higher frequency of extrathyroidal invasion
 - Other growth patterns may be seen, including follicular, papillary (classic), multiple patterns of growth, and diffuse sclerosing.
- Significance of radiation exposure to genesis of medullary thyroid carcinoma is not known, although a small number of individual cases of medullary carcinoma have occurred in patients with a history of radiation exposure to the neck.
- No evidence that ^{131}I therapy causes thyroid neoplasms.

Drug-Induced Thyroiditis

- Ingestion of certain medicines may be associated with the development of thyroiditis; however, prior to indicting any drug as causing thyroiditis, a detailed history and physical exam to include other possible causes of thyroiditis must be excluded.
- Medicinal agents implicated in the development of thyroiditis include iodides, lithium salts, phenytoin, amiodarone, and bromide.

Iodide

- Iodide is used in preparation of patients for surgery, in management of thyrotoxic storm, and as an adjunct after radioiodine therapy.
- Action of iodide includes:
 - Decrease iodide transport
 - Decrease iodide oxidation and organification
 - Rapidly blocks the release of T_4 and T_3 from thyroid
- In patients with preexisting thyroid disease such as toxic nodular goiter, iodide may worsen the hyperthyroidism (Jod-Basedow phenomenon or iodine-induced hyperthyroidism).
- Patients with hyperthyroidism due to Graves disease may have exacerbation of their hyperthyroid condition with iodide therapy.
- In patients with a goiter (endemic or sporadic), iodide added to diet may induce hyperthyroidism.
- Iodine-induced goiter and hypothyroidism occur most often in individuals with pre-existing thyroid disease (patients with chronic lymphocytic [Hashimoto] thyroiditis or treated Graves disease) or thyroid ablative therapy (thyroidectomy or radioiodine):
 - In these patients, hypothyroidism occurs with prolonged use of iodide or even following small doses of iodide, but hypothyroidism is transient and thyroid function returns to normal following cessation of iodide use.
 - Iodine-induced goiter and hypothyroidism may occasionally occur in fetus or neonate secondary to transplacental passage of iodide that was administered to the mother.
- Chronic iodide ingestion may lead to diffuse hyperplasia with papillary growth and lymphocytic cell infiltrate.

Lithium Salts (Fig. 27-47)

- Lithium is used in treatment of manic-depressive disorders.
- Effects of lithium on thyroid are similar to those of iodide and include:
 - Inhibition of thyroid hormone release
 - Inhibition of organification of iodine; the exact mechanisms of lithium's inhibitory action remain uncertain
- In a small percentage of patients (from 5% to 15%), chronic lithium (5 years or more) use may be associated with:
 - Development of a goiter
 - Development of hypothyroidism
 - Both
- Although incidence of lithium-induced hypothyroidism is considered low, it is sufficiently high enough

**Fig. 27-47.**

Lithium-associated changes of the thyroid gland show similar changes to those seen in radiation-treated glands.

A, Nodular hyperplasia with associated fibrosis. **B**, *Left panel*, nodules characterized by increased cellularity and associated dense fibrosis; *right panel*, bizarre-appearing nuclei characterized by nucleomegaly, pleomorphism, and hyperchromasia.

to warrant monitoring of patients who are receiving long-term lithium therapy.

- Histologic changes of lithium include:
 - Diffuse hyperplasia with associated nuclear pleomorphism
 - Similar to chronic lymphocytic (Hashimoto) thyroiditis and include:
 - Lymphocytic cell infiltrates with or without germinal centers, follicular epithelial cell atrophy with or without oncocyctic metaplasia, and fibrosis.
- Presence of antithyroid antibodies appears to be higher in patients with lithium-associated hypothyroidism (subclinical or overt) than those without hypothyroidism.

Anticonvulsant Drugs

- Phenytoin and carbamazepine are used in treatment of epilepsy.

- Mode of action is to reduce serum total and free T_4 , and less so T_3 , levels
 - Serum TSH concentrations are not elevated, but adding lithium to therapy will raise serum TSH levels.
- Clinically significant hypothyroidism associated with these anticonvulsants is uncommon.
- Phenytoin is associated with systemic immune reactions, and an organ-specific reaction (i.e., thyroiditis) may represent a component of the phenytoin-associated autoimmunity.

Amiodarone

- Amiodarone is used in treatment of cardiac arrhythmias and angina.
- Amiodarone tablets contain a large percentage of iodine and there is excess iodine release during the metabolism of this drug.
- Effects of amiodarone on thyroid include:
 - Iodide-related inhibition of thyroid hormone synthesis and secretion
 - Impaired cellular uptake of thyroid hormones
- Amiodarone-induced thyrotoxicosis (AIT) may occur either:
 - In presence of underlying thyroid disease referred to as Type I AIT:
 - Caused by an exacerbation by iodine load of thyroid autonomous function
 - In apparently normal thyroid glands referred to as Type II AIT
 - Probably consequent to drug-induced destructive thyroiditis
 - Mixed or indeterminate forms of AIT encompassing several features of AIT I and AIT II may also be observed.
- Abnormal thyroid function occurs in nearly all patients receiving amiodarone.
- Amiodarone may cause hypothyroidism or hyperthyroidism.
- Symptomatic hypothyroidism:
 - Usually occurs within first year of treatment but may occur later
 - Amiodarone-related (fatal) myxedema coma can occur.
 - Is associated with elevated circulating antithyroid antibodies, and this form of hypothyroidism may be related to an underlying autoimmune thyroiditis
- Amiodarone-induced hyperthyroidism may be a result of follicular cell damage with subsequent thyroid antibody production (antithyroglobulin or antimicrosomal) and/or may induce a thyroid-specific autoimmunity.
- Histologic changes may include follicular epithelial cell degenerative changes with vacuolization and a lymphohistiocytic cell response.

- Discontinuing use of drug often reverses adverse effects.
- Treatment:
 - AIT I usually responds to combined thionamide and potassium perchlorate (KClO₄) therapy.
 - AIT II generally responds to glucocorticoids.
 - Indeterminate forms may require both therapeutic approaches.
 - In patients with AIT I definitive treatment of hyperthyroidism by administration of ¹³¹I advised after normalization of iodine overload
 - To control severe AIT additional treatment with lithium carbonate, use of a short course of iopanoic acid and plasmapheresis has also been proposed.
 - In cases resistant to medical treatment and/or in patients with severe cardiac diseases, total thyroidectomy may be proposed after rapid correction of thyrotoxicosis with combination of thionamides, KClO₄, corticosteroids, and a short course of iopanoic acid.

Autoimmune Thyroid Disease (AITD)

Definition: Broad spectrum of non-neoplastic thyroid diseases with immunologic cause that usually occurs when there is failure of T-cell tolerance as a result of a combination of genetic and nongenetic factors.

- AITD includes two major forms:
 - Graves disease
 - Autoimmune thyroiditis or chronic lymphocytic (Hashimoto) thyroiditis
- AITD (Graves disease and chronic lymphocytic [Hashimoto] thyroiditis) represents:
 - Complex diseases caused by interaction between susceptibility genes and environmental triggers:
 - Genetic susceptibility in combination with external factors (e.g., dietary iodine) believed to initiate autoimmune response to thyroid antigens
 - Epidemiologic data, including family and twin studies, point to a strong genetic influence on the development of AITD.
 - Clinically distinct syndromes share common immunopathogenic mechanisms.
 - Hallmarks include thyrotoxicosis and hypothyroidism.
 - Both characterized by lymphocytic infiltration of thyroid and production of thyroid autoantibodies
 - AITDs are prototypical organ specific autoimmune diseases, but mechanisms that trigger autoimmune response to thyroid are still unclear.
- Although these diseases contrast clinically, their pathogenesis involves shared immunogenetic mechanisms.
 - Genetic data point to involvement of shared and unique genes.
 - Among shared susceptibility genes, *HLA-DRβ1-Arg74* (human leukocyte antigen DR containing an arginine at position β74) confers strongest risk.
 - Recent genome-wide analyses revealed new putative candidate genes.
 - Epigenetic modulation is emerging as a major mechanism by which environmental factors interact with AITD susceptibility genes.
- Of known environmental factors, infection, diet, iodine, and smoking appear most important.
- Considerable progress made in unraveling genetic risk factors for AITD:
 - Originally, only major histocompatibility complex (MHC) class II genes were shown to predispose to AITD.
 - However, several non-MHC susceptibility genes now confirmed to contribute to cause of AITD
 - Some genes are unique for Graves disease:
 - Thyroid-stimulating hormone receptor gene (*TSHR*), *CD40*, *CD25*
 - Some genes unique for chronic lymphocytic (Hashimoto) thyroiditis:
 - 12q (*BTG1*)
 - Some common to both diseases
 - *HLA-DRβ1-Arg7*, *CTLA-4*, *PTPN22*, thyroglobulin gene (*Tg*), *ARID5B*
- Certain genes are common to AITD and other autoimmune diseases.
- Epigenetic influences also identified in cause of AITD, including:
 - DNA methylation
 - Histone modifications
 - RNA interference by microRNA
- In support of including Graves disease and chronic lymphocytic (Hashimoto) thyroiditis as AITD include:
 - Existence of cases sharing features of both diseases, suggesting one may evolve into other:
 - In this scenario immune mediated insult leads diffuse or nodular hyperactivity (i.e., Graves disease), eventually leading to atrophy with oncocyctic cytoplasmic changes of follicular epithelium (i.e., chronic lymphocytic [Hashimoto] thyroiditis).
 - Rare occurrence in which Graves disease occurs following chronic lymphocytic (Hashimoto) thyroiditis with hypothyroidism
- Any lymphocytic infiltrate in thyroid gland is abnormal but is not necessarily an indication of AITD:

- Lymphocytic infiltrate in thyroid glands may be nonspecific (absence of clinical or laboratory findings indicating thyroid disease) and found in glands removed for other reasons representing chronic (focal) lymphocytic thyroiditis.

Chronic (Focal) Lymphocytic Thyroiditis (Fig. 27-48)

Definition: Focal (dense) collections of lymphocytes in thyroid gland incidentally identified in thyroid glands excised for other reasons in absence of clinical or laboratory findings indicating thyroid disease.

Synonym: Nonspecific lymphocytic thyroiditis

Clinical

- Rather common
- More common in women than men; most common in older-age patients
- No specific clinical findings (symptoms)
 - Clinical features correlate to the dominant pathologic process (e.g., nodules, tumor, other) in which the lymphocytic thyroiditis is a secondary finding.
- Thyroid function as determined by laboratory testing is usually within normal limits (euthyroid), although some patients may be hypothyroid but without clinical manifestations of hypothyroidism.
- Laboratory evidence of autoimmune thyroiditis (presence of antithyroid antibodies) usually absent or low levels detected

Pathology

Gross

- No specific findings:
 - Represents incidental finding that does not produce any mass lesion(s)

Histology

- Focal or multifocal aggregates of mature lymphocytes:
 - Typically germinal center formation not present but may present
- No quantitative (total number of lymphocytes) parameters required to diagnose lymphocytic thyroiditis:
 - Any lymphocytic cell infiltrate in thyroid considered abnormal, usually nonspecific, representing chronic (focal) lymphocytic thyroiditis
- Associated fibrosis, oncocyctic cytoplasmic change of follicular epithelial cells, and follicular cell atrophy typically not present but may be seen to a limited extent in any given case

Fig. 27-48. Chronic (focal) lymphocytic thyroiditis.

Incidentally identified lymphocytic infiltrate in the thyroid gland that may include **(A)** focal aggregate of mature lymphocytes without germinal center formation or **(B)** multifocal aggregates of mature lymphocytes with germinal center formation. **C**, Lymphoid aggregate in association with histologically normal appearing thyroid follicular epithelial cells.

Differential Diagnosis

- Generally not a diagnostic dilemma
- Chronic lymphocytic (Hashimoto) thyroiditis
- Malignant lymphoma

Treatment and Prognosis

- No specific treatment required
 - Treatment directed at main pathologic process to which focal lymphocytic thyroiditis secondarily found
- Excellent prognosis with no specific prognostic parameters

Autoimmune Thyroiditis or Chronic Lymphocytic (Hashimoto) Thyroiditis (Figs. 27-49 through 27-53)

Definition: Autoimmune thyroid disease characterized by goiter and elevated circulating thyroid antibodies often associated with hypothyroidism due to thyroid destruction by autoimmune process and/or presence of thyroid-stimulating hormone-blocking antibodies.

Synonyms: Goitrous thyroiditis; struma lymphomatosa; classic form of autoimmune thyroiditis; lymphadenoid goiter; “classic” Hashimoto thyroiditis

- Considered most common autoimmune disease
- Autoimmune thyroiditis includes several different clinical entities (Box 27-8); most important include:
 - Chronic lymphocytic (Hashimoto), goitrous thyroiditis or “classic” Hashimoto thyroiditis
 - Chronic atrophic thyroiditis
 - In addition several other clinicopathologic entities recognized, including:
 - Fibrous variant
 - IgG4-related thyroiditis (distinct from fibrous variant; see Fibrous Variant below)
 - Juvenile form
 - Painless thyroiditis (sporadic or postpartum)
 - Hashitoxicosis
- All forms characterized pathologically by infiltration of thyroid gland by lymphocytic and plasma cell infiltrate in interstitium among thyroid follicles,

although specific features can be recognized in each variant.

- Diagnosis relies on demonstration of circulating antibodies to thyroid antigens (mainly thyroperoxidase and thyroglobulin) and reduced echogenicity on thyroid sonogram in a patient with proper clinical features.

Clinical

- Much more common in women than in men (10:1); frequency increases with age but may occur over wide age range:
 - Rare in children but represents most common cause of sporadic goiter in children
- Wide variation in clinical features:
 - Many patients present with no signs or symptoms and diagnosis made on basis of laboratory tests of thyroid function, screening done for thyroid antibodies or incidentally found in thyroid glands surgically excised for other reasons
 - Presentation may include presence of mass lesion (goiter):
 - Typically, there is bilateral diffuse symmetric enlargement of the thyroid.
 - Infrequently, dominant mass lesion confined to one lobe may be seen, simulating neoplastic proliferation.
 - In some patients, an enlarged thyroid is the only clinical manifestation.
 - Signs of tracheal, esophageal, or recurrent laryngeal nerve compression uncommonly occur.
 - Feeling of tightness in neck is common but tenderness and pain are uncommon.
- In many patients, clinical evidence of hypothyroidism is present (see previous discussion under Hypothyroidism):
 - May occur in patients who are euthyroid
 - Rarely occurs in patients with hyperthyroidism
 - In patients who are not hypothyroid at presentation, evidence of hypothyroidism may develop with time.
- Laboratory evidence of hypothyroidism includes:
 - Overt hypothyroidism:
 - High serum TSH levels
 - Low serum free thyroxine (T_4) levels
 - Possibly decreased free triiodothyronine (T_3), although the latter may be normal
 - Subclinical hypothyroidism:
 - High serum TSH levels
 - Normal serum free T_4 levels
- Laboratory evidence of autoimmune thyroiditis includes presence of two principal autoantibodies:
 - Anti-thyroglobulin antibodies
 - Anti-thyroid peroxidase (antimicrosomal) antibody

BOX 27-8 Types of Autoimmune Thyroiditides

- Chronic lymphocytic (Hashimoto) thyroiditis (autoimmune thyroiditis)
- Fibrous variant of chronic lymphocytic (Hashimoto) thyroiditis
- IgG4-related thyroiditis
- Fibrous atrophy or atrophic thyroiditis (primary myxedema)
- Juvenile type of lymphocytic thyroiditis
- Silent (“painless”) thyroiditis
- Postpartum thyroiditis
- Chronic nonspecific (focal) lymphocytic thyroiditis

Fig. 27-49. Chronic lymphocytic (Hashimoto) thyroiditis.

Hashimoto thyroiditis (chronic lymphocytic thyroiditis). **A**, Transverse sonographic image shows subcentimeter micronodules ranging from 0.1 to 0.80 cm in size throughout the right lobe of the thyroid gland (calipers). These micronodules characteristic of Hashimoto thyroiditis are hypoechoic and surrounded by mildly echogenic rims. **B**, A different patient with chronic lymphocytic thyroiditis shows findings similar to those of the patient in **A**. **C**, Axial CT scan shows a moderately enlarged thyroid gland with a mottled, slightly nonhomogeneous appearance. This is a typical finding in Hashimoto disease. There is also scattered adenopathy, which is another expected finding in this disease. **D**, Coronal T1-weighted MR image shows a diffusely enlarged thyroid gland. Although this is a nonspecific finding, it is a typical finding in Hashimoto disease. (From Som and Curtin: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Figs. 41-33, 41-34 and 41-35, pages 2630-2631.)

- Other components of thyroid tissue may serve as autoantigens, including:
 - Thyrotropin (TSH) receptor
 - Less commonly, sodium/iodide cotransporter and pendrin
- Precise antigen(s) that cause autosensitization are unknown but presence of anti-thyroglobulin and anti-thyroid peroxidase antibodies suggest these antigens as being involved:
 - Thyroglobulin and thyroid peroxidase share epitopes; it is possible that initial antigen may result in a sequential response to other antigen(s).
 - Patients with AITD (chronic lymphocytic [Hashimoto] thyroiditis, Graves disease) show a higher prevalence of autoantibody not only against thyroid-specific but also nonthyroid-specific antigens (antibodies to nucleus, smooth muscle and

Fig. 27-50. Fine-needle aspiration biopsy in chronic lymphocytic (Hashimoto) thyroiditis.

A, Aspirate is characterized by a prominent mixed lymphoplasmacytic infiltrate. Follicular epithelium is frequently scanty and may exhibit oncocytic cytoplasmic change as well as nuclear enlargement, and variable nuclear pleomorphism. The epithelium is usually arranged in sheetlike fragments. In more florid cases colloid may be difficult to identify (Papanicolaou stain). **B**, Follicular epithelial cells appear in small clusters characterized by abundant eosinophilic granular cytoplasm (oncocytes), large nuclei, and variably sized nucleoli. **C**, Anisonucleosis may be prominent (Diff-Quik).

Fig. 27-51. Chronic lymphocytic thyroiditis (Hashimoto thyroiditis), resection specimen.

Symmetrically enlarged thyroid gland characterized by multilobulated appearance; the lobules are tan-white and replace most of the thyroid parenchyma.

single-stranded DNA) than matched control patients.

- In contrast to Graves disease, in which thyroid-stimulating antibody is almost always present, this antibody is only occasionally present in chronic lymphocytic (Hashimoto) thyroiditis.
- Patients with chronic lymphocytic (Hashimoto) thyroiditis have increased incidence of different HLA-DR haplotypes, including HLA-DR3, DR4, and DR5.
 - Patients with HLA-DR2 and HLA-DQ1 have protective effect against AITD.
- Additional laboratory findings:
 - No elevation of serum IgG and/or IgG4 levels
- Radiology:
 - Ultrasound: variety of patterns may be seen including normal glandular enlargement or diffuse abnormality with heterogeneous echogenicity:
 - In end-stage disease, gland may appear atrophied and fibrotic resulting in heterogeneous echotexture.
 - CT:
 - Inhomogeneous distribution of iodine

Fig. 27-52. Chronic lymphocytic (Hashimoto) thyroiditis.

A, Histologic features include the presence of diffuse involvement of the thyroid gland by a lymphocytic cell infiltrate with or without germinal centers, and atrophy of thyroid follicles; in this example there is an absence of fibrosis. **B**, Another case showing nodularity and associated fibrosis but the amount of fibrosis is limited with slight to moderate thickening in interlobular septa. **C**, Diffuse lymphocytic cell infiltrate with germinal center formation and associated follicular atrophy. **D**, Follicular epithelial cell showing oncocytic cytoplasmic change. **E**, Oncocytic follicular cells are characterized by the presence of a prominent granular eosinophilic cytoplasm that may be associated with nuclear enlargement, prominent eosinophilic nucleoli, and dispersed to optically clear-appearing nuclear chromatin. These changes may be misinterpreted as those of papillary thyroid carcinoma (PTC), but the distribution pattern of the follicular cells in a background of diffuse lymphocytic cell infiltrate is not the usual feature seen in PTC and, more importantly, the constellation of cytomorphicologic (nuclear) features associated with PTC are absent.

Fig. 27-53. Follicular epithelial dysplasia.

In chronic lymphocytic (Hashimoto) thyroiditis, especially in severe cases, foci with more pronounced cytological atypia may be identified. **A** and **B**, Such changes in these follicular cells with oncocytic cytoplasmic change include nucleomegaly and hyperchromasia.

- MR:
 - T2-weighted images show areas of increased signal intensity.
 - Following contrast administration, regions that enhance more than other regions of the gland may be seen.
- Pathogenesis includes genetic and nongenetic factors:
 - Genetic factors:
 - Major histocompatibility complex (MHC) class II genes:
 - Encode products that delete autoreactive T-cells, select for presentation of autoantigenic peptides, or activate suppressor T-cells
 - Other MHC genes:
 - Potential effects on antigen presentation
 - Cytokine tumor necrosis factor and some complement components also encoded in MHC
 - T-cell response genes:
 - Cytotoxic lymphocyte antigen-4 (CTL4) important in terminating T-cell activation:
 - Polymorphic variants may fail to control autoreactive T-cells fully.
 - *PTPN22* encodes T-cell activation inhibitor.
 - Interleukin-2 receptor alpha chain (*IL2RA*) encodes receptor for T-cell-activating cytokine IL-2.
 - Other immune response genes:
 - *CD40* encodes stimulatory signal for B-cells.
 - Tissue autoantigen genes:
 - Polymorphisms in genes encoding thyrotropin (TSH) receptor and thyroglobulin may predispose to distinct types of AITD.
 - Epidemiologic data, including family and twin studies, point to strong genetic influence in development of AITD.
 - Nongenetic factors:
 - Infectious agents:
 - May release autoantigens, alter expression of surface molecules, directly affect immune system, or contain immunologic sequences (epitopes) that mimic autoantigens
 - Dietary factors:
 - Diverse potential effects:
 - Iodide may enhance immunogenicity of thyroglobulin, alter thyroid-cell function, or form toxic metabolites with oxygen
 - Vitamin D deficiency may predispose to development of autoimmune disease through effects on dendritic cells and T-cells.
 - Toxins, pollutants:
 - Diverse potential effects
 - Hormones:
 - Diverse potential effects:
 - Estrogens enhance most immune responses.
 - Glucocorticoids, androgens suppress immune responses
 - Stress:
 - May alter neuroendocrine interactions with immune system
 - Drugs:
 - Diverse potential effects on immune system:
 - Lithium, interferon- α , interleukin-1 β , and some other cytokines exacerbate or promote progression of autoimmune thyroiditis.

- AITD may appear as part of immune reconstitution syndrome after bone marrow transplantation from affected donor, alemtuzumab (monoclonal antibody against CD52) treatment, or highly active antiretroviral treatment for HIV infection.
 - Familial association:
 - Up to 5% of first-degree relatives with chronic lymphocytic (Hashimoto) thyroiditis have anti-thyroid antibodies.
 - Association with other diseases:
 - High prevalence with Down syndrome, Turner syndrome, and familial Alzheimer disease
 - Patients with chronic lymphocytic (Hashimoto) thyroiditis are at greater risk of having other coexisting autoimmune diseases, including:
 - Endocrine:
 - Insulin-dependent diabetes mellitus, Addison disease (adrenal insufficiency), autoimmune oophoritis, hypoparathyroidism, and hypophysitis
 - Chronic lymphocytic (Hashimoto) thyroiditis is well-recognized component of autoimmune polyglandular syndromes (APS), which are:
 - Heterogeneous group of rare diseases characterized by autoimmune activity against more than one endocrine organ, although nonendocrine organs can be affected; two major types of APS include APS-1 and APS-2; both have Addison disease as a prominent component
 - Major autoimmune polyendocrine syndromes have a strong genetic component with the type 2 syndrome occurring in multiple generations and type 1 syndrome in siblings.
 - Autoimmune polyendocrine syndrome-type 2 (APS-2) also referred to as Schmidt syndrome:
 - Most common form of polyglandular failure syndromes
 - Patients at higher risk when they carry a particular human leukocyte antigen genotype (*DQ2*, *DQ8*, and *DRB1*0404*)
 - Affects women to a greater degree than men (75% occur in women)
 - Major components include (two major components are required to qualify as the syndrome): autoimmune thyroid disease (Graves disease; chronic lymphocytic [Hashimoto] thyroiditis), Addison disease (autoimmune adrenalitis), type 1 diabetes mellitus
 - Other components may include pernicious anemia, primary hypogonadism (less common), vitiligo, celiac disease, myasthenia gravis.
 - Major components of autoimmune polyglandular syndrome type 1 (APS-1) include:
 - Addison disease
 - Hypoparathyroidism
 - Chronic mucocutaneous candidiasis
 - In APS-1, chronic autoimmune thyroiditis occurs in 10% to 15% of patients.
 - Nonendocrine:
 - Sjögren syndrome, myasthenia gravis, pernicious anemia, thrombocytopenic purpura
- Chronic lymphocytic (Hashimoto) thyroiditis and Graves disease share common features, including:
 - Aggregation of both conditions in same families or within the same thyroid gland
 - Cases of identical twins in which one twin has chronic lymphocytic [Hashimoto] thyroiditis and other has Graves disease
 - Lymphocytic infiltration and various immunoglobulins found within thyroid in both disorders
 - Thymic enlargement and thyroid autoantibodies are found in both diseases.
 - Graves disease may evolve into chronic lymphocytic (Hashimoto) thyroiditis with hypothyroidism, and, rarely, chronic lymphocytic (Hashimoto) thyroiditis (with or without hypothyroidism) may evolve into Graves disease with hyperthyroidism.
 - In spite of these shared features, there are sufficient differences (genetic, clinical, immunologic, and pathologic) to consider these diseases as distinctly different and not the opposite ends of spectrum of a single entity.

Pathology

Fine-Needle Aspiration Biopsy

- Usually cellular consisting of mixed population of follicular cells with oncocytic cytoplasm (so-called Hürthle cells) and lymphocytes with minimal to absent colloid
- Follicular epithelial cells:
 - Usually appear in sheets or small clusters but may appear as single cells
 - Oncocytic cells characterized by abundant eosinophilic granular cytoplasm, large nuclei, and prominent nucleoli
 - Anisonucleosis may be prominent.
 - Mild nuclear atypia, nuclear clearing, and grooves may be present.
- Mixed inflammatory cell infiltrate, including mature lymphocytes, larger reactive lymphoid cells, and plasma cells:
 - Macrophages and multinucleated giant cells may be present.

- Presence of germinal centers may be reflected by a variety of lymphocytes and tingible body macrophages.

Gross

- Diffusely enlarged gland with firm consistency, pale, and irregular or bosselated surface:
 - Enlargement usually symmetric
 - Pyramidal lobe may be prominent.
 - Usually weighs 2 to 3 times more (e.g., 40 g) than normal weight
- Cut surface, gland appears tan-yellow characterized by prominent multilobulated appearance:
 - Lobules tend to bulge from cut surface and are separated by fibrous tissue.
- Bilateral diffuse thyroid enlargement, as compared to a single dominant mass, assists in decreasing clinical suspicion for neoplastic proliferation.
- Thyroid is not adherent to surrounding structures.

Histology

- At low magnification, lobules or nodules are seen separated by fibrous tissue.
- Histologic hallmarks associated with chronic lymphocytic (Hashimoto) thyroiditis include:
 - Diffuse involvement of thyroid gland
 - Mature lymphocytic cell infiltrate with or without germinal centers
 - Atrophy of thyroid follicles
 - Oncocytic metaplasia of follicular epithelial cells

NOTE: Diagnosis of chronic lymphocytic (Hashimoto) thyroiditis is one made on a combination of clinical, laboratory, and morphologic findings and should not be a diagnosis purely made on morphologic grounds.

- Inflammatory cell infiltrate:
 - Composed primarily of mature lymphocytes with admixed mature plasma cells:
 - Distributed within and around lobules
 - Often prominent germinal centers are present.
 - T-cells predominate over B-cells.
 - In addition, macrophages and giant cells may be present:
 - Giant cells are seen within the follicles but are limited in extent and number unlike those present in subacute thyroiditis and a neutrophilic infiltrate is not seen.
- Thyroid atrophy includes presence of small follicles with limited to absent colloid formation.
- Fibrosis within and around follicles:
 - Interlobular fibrosis gives gland a nodular appearance.
 - Amount of fibrosis usually scanty with slight to moderate thickening in interlobular septa
 - Fibrosis not usually extensive as seen in fibrous variant (see later in chapter) or as identified in Riedel thyroiditis

- Does not extend outside the thyroid gland
- Rare examples of coexisting chronic lymphocytic (Hashimoto) thyroiditis and Riedel thyroiditis
- Oncocytic cytoplasmic change:
 - Characterized by cells with prominent granular eosinophilic cytoplasm (so-called Hürthle cells)
 - Often associated with nuclear enlargement, prominent eosinophilic nucleoli, and dispersed to optically clear-appearing nuclear chromatin
 - These changes may be confused with those of papillary thyroid carcinoma but additional architectural and/or cytomorphologic are absent, including but not limited to variation in nuclear size and shape.
 - Foci with more pronounced cytological atypia may be identified that some authors have variably termed atypical follicular epithelium, atypical cell clusters, or follicular epithelial dysplasia (FED):
 - Particularly prominent in cases of severe chronic lymphocytic (Hashimoto) thyroiditis but lack invasive growth, papillary architecture, or intranuclear pseudoinclusions
- Additional changes that can be seen include:
 - Squamous metaplasia of follicular epithelial cells (more common in the fibrous variant; see below)
 - Intrathyroidal cysts:
 - Squamous epithelial cell-lined
 - Ciliated respiratory epithelial-lined:
 - May attain fairly large sizes and bordered by lymphocytic infiltrate, suggesting branchial cleft cysts
 - Similar cysts can be seen in absence of thyroiditis.
- Immunohistochemistry:
 - Lymphoid infiltrate includes:
 - Reactivity for B-cell (CD20) and T-cell (CD3) markers
 - B-cells and plasma cells exhibit kappa and lambda staining (i.e., lack light chain restriction) and exhibit IgG, IgM, and IgA heavy chains.
 - B-cells are most often of the IgG kappa type.
 - Follicular epithelial cells:
 - Focal expression of HBME1, galectin3 (GAL3), cytokeratin 19 (CK19):
 - Similar expression profile may be seen in papillary thyroid carcinoma.
 - In contrast to papillary thyroid carcinoma, diffuse expression of HBME1, GAL3, CK19 not present in chronic lymphocytic (Hashimoto) thyroiditis
 - Further, immunoreactivity for HBME1, GAL3, and CK19 not specific or sensitive for papillary thyroid carcinoma

- So-called follicular epithelial dysplasia (FED) reported to be immunoreactive for:
 - Thyroglobulin and TTF-1
 - p63 (26 %)
 - Strong diffuse staining for HBME-1 (86 %), CK19 (96 %), galectin-3 (40%)
 - Immunohistochemical profile similar to papillary thyroid carcinoma (PTC) supporting concept of premalignant lesion preceding PTC arising in context of severe chronic inflammation
 - However, absence of *BRAF* mutation in HBME1 and CK19 positive atypical cell clusters or FEDs in chronic lymphocytic (Hashimoto) thyroiditis support that they may not be preneoplastic.
- Cytogenetics and molecular genetics:
 - Presence of RET/PTC rearrangements reported even in absence of morphologic findings diagnostic for papillary thyroid carcinoma:
 - This finding coupled with reports showing immunohistochemical comparable features to those of papillary thyroid carcinoma (see above) suggest possibility of early, focal premalignant transformation in some cases of chronic lymphocytic (Hashimoto) thyroiditis.
 - Despite above findings reported in literature, from a practical perspective, absence cytomorphic (i.e., nuclear features) reaching level diagnostic for papillary thyroid carcinoma preclude such a diagnosis, and the concept of early, focal premalignant transformation remains to be proven.
 - Absence of *BRAF* mutation in areas with atypical cell clusters or FEDs suggest:
 - *BRAF* is less frequent mechanism of tumorigenesis in background of chronic lymphocytic (Hashimoto) thyroiditis
 - *BRAF* mutation not present in the atypical cell clusters or FEDs

Differential Diagnosis

- Non-Hodgkin malignant lymphoma
 - In contrast to neoplastic lymphoid population of thyroid gland malignant lymphoma, lymphocytic cell infiltrate of chronic lymphocytic (Hashimoto) thyroiditis:
 - Is confined to thyroid gland and does not extend beyond the thyroid capsule into perithyroidal soft tissue
 - Presence of “colonization” of thyroid follicles (as appears in malignant lymphoma) may occur but usually is absent.
- Papillary thyroid carcinoma:
 - See above.

Treatment and Prognosis

- Thyroxine (T_4) therapy is preferred treatment for all patients with hypothyroidism (overt or subclinical) as a result of autoimmune thyroiditis:
 - Treatment generally is lifelong as hypothyroidism will recur with cessation of thyroxine.
 - Proper response to T_4 therapy will include a decrease in levels of thyroid antibodies.
- Immunosuppressive (corticosteroid) therapy may result in regression of thyroid enlargement and decrease in thyroid antibody levels; however, due to serious side effects of steroids and the efficacy of thyroxine therapy, immunosuppressive therapy is not indicated.
- Appropriate therapy for patients who are euthyroid but have enlarged glands (goiter) remains uncertain.
 - T_4 administration may result in a decrease in the size of the gland, whereas in others there will be no diminution in size but rather progressive enlargement of the thyroid.
 - Further, up to 10% to 15% of patients may become hypothyroid.
- Surgery can be used in those patients who do not respond to thyroxine therapy and have continued enlargement (with or without local symptoms) of their thyroid glands.
- Graves disease may follow (or precede) chronic lymphocytic (Hashimoto) thyroiditis.
- Patients with coexisting thyrotoxicosis should be treated accordingly.
- Complications include potential development of:
 - Hematolymphoid malignancy (lymphoma or leukemia)
 - Strong association with primary B-cell lymphoma of thyroid gland
 - Presumably due to prolonged stimulation of intrathyroidal B-cells resulting in malignant clone
 - Follicular epithelial-derived tumors, including:
 - Papillary thyroid carcinoma
 - Follicular carcinoma
 - Patients with autoimmune thyroiditis are at no increased risk of developing a thyroid neuroendocrine neoplasm (i.e., medullary thyroid carcinoma), although coincidental medullary thyroid carcinomas may occur in setting of chronic lymphocytic (Hashimoto) thyroiditis.

Fibrous Variant of Chronic Lymphocytic (Hashimoto) Thyroiditis (Figs. 27-54 through 27-56)

Synonym: Advanced lymphocytic thyroiditis

- Makes up approximately 10% to 12% of all cases
- As compared to the “classic type,” fibrous variant is:

Fig. 27-54. Fibrous variant of chronic lymphocytic (Hashimoto) thyroiditis.

Resection specimen showing a diffusely enlarged thyroid that was firm to hard with grossly identifiable (white) fibrotic areas creating a prominent nodular/lobulated appearance.

- More common in men than in women
- Occurs in older-age patients
- Patients present with symptoms of large goiter that may produce dysphagia and dyspnea.
- Laboratory findings:
 - High titers of antithyroglobulin antibodies
 - Severe hypothyroidism
 - Elevated serum TSH levels
- Relationship to IgG4-related diseases:
 - Suggestion that fibrosing variant of chronic lymphocytic (Hashimoto) thyroiditis also part of spectrum of IgG4-related diseases (IgG-RD) but not unequivocally confirmed:
 - Evidence accumulating that supports including fibrosing variant of chronic lymphocytic (Hashimoto) thyroiditis but relationship to IgG4-RD remains unproven
 - Support for inclusion within spectrum of IgG4-related diseases includes:
 - Reported instances, albeit rare, of combined Riedel disease and chronic lymphocytic (Hashimoto) thyroiditis:
 - Characterized by clinical and laboratory findings of chronic lymphocytic (Hashimoto) thyroiditis and pathologic findings of Riedel disease
 - Likely a coincidental occurrence
 - 21% (5/24) patients in one study had >135 mg/dL of IgG4 representing serum criterion of IgG4-related disease.
 - Levels of IgG and IgG4 positively correlated with titers of anti-thyroglobulin antibody or anti-thyroid peroxidase antibody

- Increased numbers of IgG4-positive plasma cells and increase IgG4:IgG ratio in chronic lymphocytic (Hashimoto) thyroiditis
- Although a proportion of cases show elevated numbers of IgG4 positive plasma cells, there is an absence of histologic features typically associated with IgG4-RD (see under differential diagnosis below for histologic findings seen in IgG4-related Riedel disease but absent in chronic lymphocytic [Hashimoto] thyroiditis)
- Despite above findings, designation IgG4-related thyroiditis being suggested as distinct from fibrous variant of chronic lymphocytic (Hashimoto) thyroiditis characterized by:
 - Younger age population
 - Lower female-to-male ratio
 - Subclinical hypothyroidism
 - Diffuse sonographic echogenicity
 - Rapid progression requiring surgical treatment
 - Higher levels of thyroid autoantibodies
 - High IgG4 level in serum
 - Increased IgG4-positive plasma cells in thyroid
 - Serum IgG4 concentrations decreased significantly after thyroidectomy
 - Histopathologically, show higher grade of stromal fibrosis, lymphoplasmacytic infiltration, and follicular cell degeneration than non-IgG4 thyroiditis
 - For those cases that do not qualify as being an IgG4-related thyroiditis, terminology of non-IgG4-related thyroiditis has also been used.

Pathology

Fine-Needle Aspiration Biopsy

- Due to marked fibrosis, aspiration generally yields little material.

Gross

- Diffusely enlarged thyroid gland that is firm to hard, pale tan, and characterized by presence of fibrosis and a prominent lobular appearance
- Thyroid glands may weigh as much as 200 g or more.
- Thyroid not adherent to surrounding structures

Histology

- Characteristic features at low power include:
 - Presence of obvious nodular or lobular pattern of growth with associated dense fibrosis and a chronic inflammatory cell infiltrate
- Fibrosis:
 - Keloid-like with irregular broad bands of acellular fibrous tissue coursing in and around remnant of thyroid parenchymal tissue

Fig. 27-55. Fibrous variant of chronic lymphocytic (Hashimoto) thyroiditis.

A and **B**, The low magnification features include the presence of a nodularity, keloid-like fibrosis with irregular broad bands of acellular fibrous tissue coursing in and around remnant of thyroid parenchymal tissue, chronic inflammatory cell infiltrate (with or without germinal centers), and atrophy of the follicular epithelial cells. **C**, Keloid-like fibrosis, mixed lymphoplasmacytic cell infiltrate and atrophic thyroid follicles. **D**, Follicular epithelial cells showing oncocytic cytoplasmic change characterized by the prominent granular eosinophilic cytoplasm, nuclear enlargement, variably sized nucleoli, and dispersed to clear-appearing nuclear chromatin; associated lymphoplasmacytic cell infiltrate is present.

- Inflammatory infiltrate:
 - Includes mature lymphocytes and plasma cells (lymphoplasmacytic cell infiltrate)
 - Seen within fibrotic tissue
- Remnant of thyroid tissue shows the changes of chronic lymphocytic thyroiditis, including:
 - Mature lymphocytic cell infiltrate with or without germinal centers
 - Severe follicular atrophy
 - Oncocytic metaplasia of follicular epithelial cells
- Squamous metaplasia may be prominently seen:
 - May include keratinization and intercellular bridges and/or squamous eddies or whorls
- Mucous cell metaplasia rarely may be present.
- Immunohistochemistry:
 - Staining for IgG and IgG4 may allow for determination whether any given case might be

classified as IgG4-related thyroiditis or non-IgG4-related thyroiditis

- See discussion in Section 6, Salivary Gland, for diagnostic criteria related to IgG and IgG4 immunoreactivity.

Differential Diagnosis

- Riedel disease
 - Findings in Riedel disease that allow for separation from fibrous variant of Hashimoto thyroiditis include:
 - Extension of pathologic (fibroinflammatory) process outside the thyroid gland:
 - Occurs in Riedel disease
 - Does not occur in (fibrous variant of) Hashimoto thyroiditis

Fig. 27-56. Fibrous variant of chronic lymphocytic (Hashimoto) thyroiditis.

Metaplastic changes that may be seen in the fibrous variant of chronic lymphocytic (Hashimoto) thyroiditis include **(A and B)** squamous metaplasia including keratinization with keratohyaline granules and squamous morule and **(C and D)** mucous cell metaplasia including intracytoplasmic **(E)** mucicarmine and **(F)** diastase-resistant, periodic acid-Schiff positive material.

- Cytoplasmic oncocyctic cell changes in follicular epithelial cells:
 - Absent in Riedel disease
 - Present in (fibrous variant of) Hashimoto thyroiditis
- Vasculitis/phlebitis:
 - Present in Riedel disease
 - Absent in (fibrous variant of) Hashimoto thyroiditis
- Plasma cells:
 - In Riedel disease express lambda chains and IgA
 - In fibrous variant of Hashimoto thyroiditis predominantly express kappa chains and IgG
- Carcinoma:
 - Presence of fibrosis and associated epithelial islands showing squamous metaplasia may raise concern for possible diagnosis of thyroid squamous cell carcinoma:
 - Absence of cytomorphic features indicative of squamous cell carcinoma
 - In presence of squamous and mucous cell metaplasia consideration may be given for a diagnosis of primary thyroid mucoepidermoid carcinoma:
 - Diffuse rather than focal changes weigh against a diagnosis of mucoepidermoid carcinoma
 - Absence of significant cytologic atypia and absence of invasive growth weigh against a diagnosis of mucoepidermoid carcinoma.

Treatment and Prognosis

- Surgical removal of the thyroid (total thyroidectomy) is indicated.
- Prognosis is considered good following removal of the gland with relief of symptoms.

Fibrous Atrophy of Thyroid Gland (Atrophic Thyroiditis, Idiopathic Myxedema, Primary Myxedema)

- More common in women than in men; occurs in older-age patients
- Aside from the enlarged goitrous thyroid, clinical presentation and laboratory findings are similar to the fibrous variant of lymphocytic thyroiditis, including:
 - Severe hypothyroidism
 - High titers of antithyroglobulin antibodies
- Thyroid gland is small, often weighing from 1 to 6 g.
- Histologically:
 - Similar changes to those of fibrous variant of lymphocytic thyroiditis (but gland is much smaller), including:
 - Prominent keloid-like fibrosis
 - Chronic inflammatory cell infiltrate

- Marked follicular atrophy with oncocyctic and squamous metaplasia
- Thyroid parenchyma may not be recognizable replaced by dense tan-white fibrous tissue.

- Given the similarities in their clinical findings and histopathologic appearance, fibrous atrophy of the thyroid and fibrous variant of lymphocytic thyroiditis may be related, with former representing end stage in clinical and morphologic continuum from latter.

Juvenile Form of Chronic Lymphocytic Thyroiditis (Juvenile Autoimmune Thyroiditis; Juvenile Lymphocytic [Hashimoto] Thyroiditis)

- Much more common in females than in males; most common in adolescents and young adults
- Clinically may present with or without goiter (goitrous versus atrophic form) with or without (mild) hypothyroidism:
 - Goitrous form more common
- Some patients may present with signs and symptoms of thyrotoxicosis (tachycardia, nervousness, increased pulse pressure) rather than hypothyroidism.
- Mild to marked elevated antithyroglobulin antibodies may be present:
 - Prevalence of thyroid autoantibodies of 20% to 30% in children with type I diabetes mellitus
 - Prevalence of elevated serum TSH levels of around 10% found
 - Recommended that all children with diabetes mellitus be screened for autoimmune thyroid disease
- May be strong family history of thyroid disease (e.g., asymptomatic goiter, hypothyroidism, and Graves hyperthyroidism)
- Most commonly occurs in absence of abnormalities in another endocrine organ
 - Most common clinical entity is autoimmune polyglandular syndrome type 2 (APS-2) or Schmidt syndrome, characterized by a combination of Hashimoto thyroiditis and lymphocytic adrenalitis resulting in adrenal insufficiency (Addison disease).
- Histologically characterized by:
 - Lymphoplasmacytic infiltrate
 - Oncocyctic cytoplasmic changes of follicular epithelial cells
 - Focal or absent follicular atrophy
 - Squamous metaplasia may be present.
- Follicular epithelial hyperplasia may be present, correlating with a hyperthyroid state.

- Variable biology including spontaneous remission, progressive atrophy of thyroid with progression to (severe) hypothyroidism or recurrent hyperthyroidism

Painless (“Silent”) Thyroiditis with Hyperthyroidism

- Primarily affects women in younger age groups at puerperium or postpartum
 - May occur in men
- Patients present with:
 - Painless, nontender thyroid gland
 - Elevated levels of free T_4 and T_3
 - Elevated antithyroglobulin antibodies
 - Episodic hyperthyroidism
 - Low radioactive iodine uptake
 - Spontaneous resolving hyperthyroidism
- Similar histomorphologic changes to juvenile form of lymphocytic thyroiditis, including:
 - Variable lymphocytic infiltration with preservation of lobular architecture:
 - Inflammatory infiltrate may be focal or diffuse.
 - Oncocytic cytoplasmic changes of follicular epithelial cells is uncommon; when present often focal
 - Fibrosis usually absent; when present is focal
 - Follicular destruction present in all cases
- Variable biology including complete resolution, recurrent hyperthyroidism or, rarely, progression to hypothyroidism
- Although initially considered a form of subacute thyroiditis, this entity differs from so-called painless “silent” subacute thyroiditis in that it:
 - Is an autoimmune disease (and belongs to the spectrum of autoimmune thyroiditides)
 - Is associated with elevated antithyroglobulin antibodies
 - Lacks histomorphologic features of subacute granulomatous thyroiditis; specifically, there is no granulomatous inflammation and/or multinucleated giant cells
 - Is associated with a greater risk of permanent hypothyroidism and a higher recurrence rate
- Associated with:
 - Antithyroid antibodies:
 - Usually antiperoxidase antibodies
 - Low serum TSH together with elevated free T_4 and T_3
 - Low radioactive iodine uptake:
 - Due to destructive nature of disease
 - Late hypothyroid phase, which may last for years:
 - Serum TSH level >3.6 mU/L with free T_4 <0.6 ng/dl
- Immunologically related disease:
 - Association with haplotypes consistent with AITD:
 - HLA-A1, -B8, HLA-A26, -BW46, -BW67
 - Lower frequency of HLA-BW62 and -CW7
 - HLA class II also present
 - Significant elevation of circulating antibodies
- Histopathology:
 - Lymphocytic infiltration
 - Slight follicular hyperplasia
 - Variable disruption of follicular cells
- Self-limiting disease:
 - Transient hypothyroid state related to depletion of thyroglobulin owing to destruction of follicular epithelial cells
- Prognosis:
 - Thyrotoxicosis always resolves.
 - Recurrence relatively common
 - Permanent hypothyroidism may develop in 20% to 30% of patients.

Hashitoxicosis (Hyperthyroiditis)

- Includes some of categories listed above, including:
 - Juvenile form of chronic lymphocytic thyroiditis
 - Painless thyroiditis with hyperthyroidism
- Patients present with clinical evidence of Graves disease (with or without laboratory confirmation) and histologically demonstrate features of chronic lymphocytic (Hashimoto) thyroiditis, including:
 - Lymphoplasmacytic infiltration with germinal centers
 - Oncocytic cytoplasmic changes of follicular epithelial cells
 - Follicular atrophy and metaplasia
- In some cases, follicular hyperplasia is present with minimal or absent follicular atrophy and oxyphilic metaplasia.

Postpartum Thyroiditis

- Affects women in first year after delivery
- Patients present with:
 - Painless, nontender thyroid gland
 - Transient thyrotoxicosis about 14 weeks postpartum followed by transient hypothyroidism
 - Occasionally hypothyroid state may develop first
 - Not all patients develop both thyroid states:
 - Thyrotoxic episode may escape detection owing to its short duration.

Graves Disease (Diffuse Toxic Goiter; Autoimmune Hyperthyroidism Disease) (Fig. 27-57 through 27-66)

Definition: Organ specific autoimmune disorder caused by production of autoantibodies characterized by

Fig. 27-57. Graves ophthalmopathy.

Diffuse hyperplasia (Graves disease). **A**, Among the more obvious clinical manifestations associated with Graves' disease patients is the presence of ophthalmopathy. **B**, Axial T2-weighted MR image of the orbits shows thickening of the muscle bellies of the extraocular muscles bilaterally. There is tapering down to normal size at the anterior tendon insertions to the globe. In addition, the muscle signal intensity is higher than normal indicating the presence of some inflammation. There is also proptosis. Thyroid ophthalmopathy. (From Som and Curtin: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 41-19, page 2621.)

variable combination of hyperthyroidism, ophthalmopathy, and dermatopathy.

Synonym: Basedow disease

- Pathogenesis:
 - Graves disease is a unique human autoimmune disease with stimulating autoantibodies to thyrotropin (TSH) receptor as major pathogenic feature:
 - These antibodies represent markers of disease but are also responsible for hyperthyroidism that occurs in these patients.

Fig. 27-58. Graves disease.

Frontal ^{131}I scintigraph of a patient with Graves disease shows diffuse increased uptake of the radiotracer throughout the gland. The 2-hour uptake was 25% and the 24-hour uptake was 57%, with the upper limits of normal being 10% and 30%, respectively. (Case is courtesy of Dr. Joseph Sam.) (From Som and Curtin: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 41-31, page 2629.)

- B- and T-lymphocytes known to be directed at three well-recognized thyroid autoantigens:
 - Thyroglobulin (Tg)
 - Thyroid peroxidase (TPO)
 - Thyroid-stimulating hormone receptor (TSHR):
 - ◻ Most evidence suggests only TSHR is primary autoantigen of Graves disease.
 - ◻ Immune responses to other thyroid antigens only reflective of concomitant thyroiditis
- Antibodies bind to thyroid-stimulating hormone receptors (TSHR) on thyroid follicular epithelial cells leading to overstimulation and enlargement of the thyroid gland with overproduction of thyroid hormones, suppression of TSH production from pituitary gland, and clinical manifestations of hyperthyroidism.
- TSHR antibody that stimulates thyroid gland was originally called long-acting thyroid stimulator (LATS).
- In patients with Graves disease, thyroid gland no longer under control of pituitary TSH but is continuously stimulated by circulating antibodies with TSH-like activity:

Fig. 27-59. Fine-needle aspiration biopsy in Graves disease.

The aspirate included high cellularity and lack of colloid in which there were flat sheets of follicular epithelial cells with abundant oncocytic appearing cytoplasm. These features may suggest a follicular neoplasm with oxyphilia. The clinical history is most helpful in arriving at a correct interpretation. Note the prominent granularity of the cytoplasm, a common feature in Graves disease (Diff-Quik stain).

Fig. 27-60. Graves disease.

Total thyroidectomy specimen in Graves disease showing diffuse symmetric enlargement of the gland, which has a beefy red appearance.

- Not possible to suppress thyroid gland using exogenous TSH because thyroid-stimulating antibodies are unaffected

Clinical

- Reported incidence in the United States from 0.02% to 0.4% of population
- Represents most common cause of hyperthyroidism, accounting for approximately 70% to 80% of all cases

Fig. 27-61. Graves disease, untreated.

- A,** At low magnification there is diffuse hyperplasia with prominent papillary architecture, solid foci with increased cellularity and relative absence of colloid with no identifiable histologically normal thyroid parenchyma.
- B,** In addition, a lymphocytic cell infiltrate including germinal centers is present.

- Much more common in women than in men; may occur at any age but is most commonly seen in the third to sixth decades of life:
 - May occur in children; in this age group Graves disease represents most common cause of hyperthyroidism
- Most patients with Graves disease have hyperthyroidism and goiter.
- Graves disease causes most florid signs and symptoms of thyrotoxicosis, including:
 - Nervousness, fatigue, muscle weakness, tremor, increased perspiration, warm and moist skin, nonpitting edematous changes of the skin, heat intolerance, palpitation, tachycardia, cardiac arrhythmia, systolic hypertension, hyperactivity, hyperreflexia, increase in appetite, loss of weight,

Fig. 27-62. Graves disease, untreated.

A, Left panel, Papillary hyperplasia may simulate the features seen in papillary thyroid carcinoma; **right,** colloid is distorted due to fixation and has a “scallop” appearance. The nuclear features in Graves disease whether **(B)** associated with papillae or **(C)** lining follicles with or without (scallop appearing) colloid are small, round to oval with smooth nuclear contours lacking the nuclear findings seen in papillary thyroid carcinoma.

Fig. 27-63. Treated Graves disease.

The involutional changes associated with radioiodine therapy include reversion of the follicular epithelial cells to their usual appearance (cuboidal to flat) with greater degree of restoration of colloid.

Fig. 27-64. Treated Graves disease.

Prolonged treatment with radioiodine therapy in Graves disease may be associated with fibrosis creating a nodular-appearing thyroid gland.

- menstrual disturbances, stare, and eyelid retraction
- Enlargement of thyroid gland:
 - Characteristically, diffuse, symmetric bilateral enlargement, but asymmetric enlargement is not uncommon
 - Lobulations or (multi)nodules can occur.
 - Glands generally not tender or painful, but these symptoms may present.
- Continuous or systolic (palpable) thrills or (audible) bruits over one or both thyroid lobes are present in a minority of patients.
- Extrathyroidal manifestations of Graves disease include:

Fig. 27-65. Treated Graves disease.

In addition to the fibrosis and nodularity, prolonged radioactive iodine therapy may result in (**A**, left and right) atypical-appearing nodules with increased cellularity and markedly bizarre-appearing nuclei (nucleomegaly, pleomorphism, and hyperchromasia); (**B**) scattered mitotic figures may be seen but generally are low in numbers and there is an absence of necrosis.

- Ophthalmopathy:
 - Proptosis or staring appearance (most common), blurred vision, diplopia, photophobia, lacrimation, retroocular pressure; histologically, there is edema, lymphocytic cell infiltration, glycosaminoglycan deposition, and fibrosis of the extraocular muscles
- Dermopathy:
 - Localized myxedema (nonpitting) resulting from circumscribed accumulations of glycosaminoglycans
 - Most frequently seen on skin of anterior lower legs (pretibial myxedema)
 - Additional forms of Graves dermatopathies include:
 - Sharply circumscribed, tuberos, or nodular lesions

- An elephantiasis form, also known as thyroid acropachy, which includes edematous and nodular thickening of the extremities; thyroid acropachy is least common Graves dermatopathy and most patients with this dermatopathy have clinically significant ophthalmopathy and localized myxedema
- Pathogenesis for Graves-associated ophthalmopathy and localized myxedema remains unclear; however, recent evidence has shown that cytokines implicated in pathogenesis:
 - In patients with autoimmune thyroid disease cytokines can be found in the thyroid gland and extrathyroidal sites.
 - Cytokines affect autoimmune process through a number of mechanisms, including recruitment of inflammatory cells and upregulation of molecules essential for perpetuation of the inflammatory response in the affected site.
 - Cytokines interfere with thyroid hormone synthesis, implicating them directly in thyroid dysfunction.
 - Cytokines can modulate function of cells in orbital tissue, which results in localized edema, indicating a central role for cytokines in development of proptosis.
- Laboratory findings:
 - Thyroid function testing:
 - Hyperthyroidism with high serum total and free thyroxine (T_4) and T_3 concentrations with increased radioactive iodine uptake in association with low serum TSH concentrations
 - T_3 predominant Graves disease is variant of Graves disease in which there is increased serum T_3 levels in presence of therapy-induced low T_4 levels.
 - In a patient with ophthalmopathy and diffuse goiter, presence hyperthyroidism is diagnostic of Graves disease, and measurements of thyroid-stimulating antibody are not needed for diagnostic purposes.
 - Pituitary-hypothalamic testing:
 - Decreased to negligible levels of thyroid-stimulating hormone and TRH (tripeptide hypothalamic hormone)
 - Autoimmune basis:
 - Presence of elevated circulating TSH receptor antibodies
 - Higher incidence of genetic predisposition to this and other autoimmune diseases
 - Presence of HLA-DR type II antigen on follicular epithelial cell surfaces
- Patients with autoimmune thyroid disease show a higher prevalence of autoantibody not only against thyroid-specific but also nonthyroid-specific antigens

Fig. 27-66. Graves disease with papillary thyroid carcinoma.

Papillary thyroid carcinoma is perhaps the most common malignant thyroid tumor that may arise in association with Graves disease. **A**, Incidentally identified microscopic focus of papillary carcinoma appearing as a small discrete nodule (*arrow*) from the surrounding diffusely hyperplastic thyroid parenchyma. **B** and **C**, At higher magnification, the nuclei of papillary carcinoma (*top*) are enlarged with irregularities in size and shape, have clear to dispersed-appearing chromatin, and show crowding and overlapping. In comparison, the nuclei in association with Graves disease (*bottom*) are small, rather uniform in shape with smooth nuclear contours, and have more hyperchromatic-appearing nuclear chromatin.

- (antibodies to nucleus, smooth muscle, and single-stranded DNA) than matched control patients.
- Radiology:
 - Most hyperthyroid patients have increased (high) radioiodine uptake.
 - In some hyperthyroid patients, there is decreased (low) radioiodine uptake, including those hyperthyroid patients with subacute thyroiditis, painless thyroiditis, exogenous hyperthyroidism, and patients receiving iodide-containing drugs.
- Risk factors:
 - Susceptibility genes:
 - Complex diseases with large number of gene loci involved
 - Susceptibility genes fall into two distinct groups:
 - Immune response genes including *HLA*, *CTLA-4*, *PTPN22*, *FCRL3*, and *CD40*
 - ◻ Associated polymorphisms in these genes are common to many autoimmune diseases.
 - Thyroid-specific genes including *TSHR* and *Tg*
 - Caused by interaction between susceptibility genes and environmental triggers
 - External factors:
 - Infection: long-standing theory suggests variety of viral infections may lead to virus becoming persistent endogenous thyroid antigen or by epigenetic influences may lead to overexpression of thyroid antigens
 - Sparse evidence related to AITD

- Nutrition
- Trauma
- Stress
- Iodine intake
- Irradiation
- Internal factors:
 - Thyroid autoantibodies:
 - Presence of anti-TPO and anti-Tg doubles risk of autoimmune thyroiditis
 - Sex steroids:
 - More women than men have Graves disease, and evidence suggests sex steroids (estrogen and progesterone) may contribute to difference in susceptibility.
 - Further, evidence in favor of sex steroid influence includes fact that Graves disease uncommon before puberty
- Pregnancy
- Genetic susceptibility

Pathology

Fine-Needle Aspiration Biopsy

- Cellular aspirate
- Orderly sheets of follicular epithelial cells with a “honeycomb” pattern
 - Nuclei enlarged but are round with regular contours, coarse nuclear chromatin, and may show prominent nucleoli
 - Cytoplasmic oncocyctic (oxyphilic) change with prominent cytoplasmic granularity:
- “Flame cells” represented by marginal cytoplasmic vacuoles with red to pink frayed edges may

be seen but are not specific for Graves disease and may be seen in other non-neoplastic thyroid lesions as well as in neoplasms (e.g., follicular adenoma and carcinoma, papillary carcinoma).

- Absent to minimal colloid
- In presence of supporting clinical history, more specific diagnoses may be used, including:
 - Consistent with chronic lymphocytic (Hashimoto) thyroiditis
- In absence of supporting clinical history, descriptive diagnosis may be used, including:
 - Numerous polymorphic lymphoid cells with admixed benign follicular cells with prominent oncocyctic cytoplasmic changes (so-called Hürthle cells) consistent with chronic lymphocytic (Hashimoto) thyroiditis in proper clinical setting

Gross

- Diffuse and symmetric enlargement of thyroid gland is norm
 - Asymmetric enlargement is not uncommon.
 - Lobulations or (multi)nodules can occur.
- Gland appears beefy red, is rubbery to firm, attaining weights of 150 g or more.

Histology (Table 27-1)

Untreated Graves Disease

- Diffuse follicular hyperplasia with prominent papillary architecture
 - Overall lobular architecture of gland is retained but there is no histologically identifiable normal thyroid parenchyma.

TABLE 27-1 Histology of Graves Disease (Untreated and Treated) Versus Papillary Carcinoma

Features	Untreated Graves Disease	Treated Graves Disease	Papillary Carcinoma, Classic Type
Extent of disease	Diffuse; affects the entire thyroid gland with no residual normal (uninvolved) thyroid tissue seen	Diffuse; affects entire thyroid gland with no residual normal (uninvolved) thyroid tissue seen	Limited; residual uninvolved thyroid tissue is present
Architecture	Diffuse hyperplasia	Variegated appearance; hyperplastic foci are haphazardly arrayed with areas in which hyperplastic changes are not present	Not a diffuse process, rather neoplastic features are focally seen; non-neoplastic (normal) thyroid is identifiable
Papillae	Simple without complex branching	Simple without complex branching	Complex branching
Colloid	Minimal to absent; scalloping is present	Restored	Present; often colloid is darker than in non-neoplastic thyroid
Cyto-morphology	Columnar appearing follicular epithelial cells with enlarged nuclei, amphophilic cytoplasm, and indistinct cell borders; nuclei are round and regular with coarse chromatin and are arranged along basal aspect of cell	In nonhyperplastic areas, there are cuboidal to flattened follicular epithelial cells	Enlarged nuclei with irregularities in size and shape; dispersed to optically clear appearing nuclear chromatin with margination of chromatin along nuclear membrane; nuclear grooves; nuclear inclusions; crowding and overlapping nuclei; loss of basal polarity of the nuclei

- Follicular epithelial cells tend to be columnar in appearance with enlarged nuclei, amphophilic cytoplasm, and indistinct cell borders:
 - Nuclear enlargement with clear appearance can be seen, potentially raising some concern relative to a diagnosis of papillary thyroid carcinoma.
 - In contrast to papillary thyroid carcinoma:
 - Nuclei are round and uniform without irregularities in size and shape, have coarse and not optically clear or dispersed nuclear chromatin pattern, retain their orientation along basal aspect of the cell and are not haphazardly arrayed with crowding or overlapping, lack many nuclear grooves, and usually lack intranuclear inclusions.
 - Papillae are simple lacking complexity in growth (branching or arborization) as seen in papillary thyroid carcinoma.
- Minimal to absent colloid production:
 - Colloid that is present may only be focally seen, not appearing in all lumens, and is artifactually distorted due to fixation creating a “scalloped” appearance adjacent to the follicular epithelial cells.
- Mature lymphocytic cell infiltrate, with or without germinal centers, seen within stroma:
 - Range from minimal to extensive
 - Mixed B- and T-cell lymphocytes:
 - T-cells predominate among epithelial cells and in interstitial tissue.
 - B-cells numerous in lymphoid follicles/germinal centers
 - Dendritic cells may be increased in numbers.
- Prominent vascularity seen
- Minimal fibrosis or sclerosis is present.
- Rarely, psammoma bodies can be seen in absence of papillary thyroid carcinoma.
- Additional changes that can be seen in long-standing cases of Graves disease include:
 - Fibrosis, oncocytic cytoplasmic change of follicular epithelial cells, and cytologic atypia including enlarged, bizarre-appearing nuclei (endocrine atypia)
- Immunohistochemistry:
 - Immunostaining for HLA-DR positive in cytoplasm of follicular epithelial cells and lymphoid cells

Differential Diagnosis

- Papillary thyroid carcinoma (see [Table 27-1](#))
- Dyshormonogenetic goiter:
 - Histology of dyshormonogenetic goiter (see later in chapter) also includes diffuse hyperplasia in absence of residual normal appearing thyroid parenchyma, but in contrast to changes in Graves disease, an associated lymphocytic infiltrate (component of Graves disease) is not a feature seen.

Treatment and Prognosis

- Medical therapy is preferred treatment and includes:
 - Antithyroid drugs:
 - Inhibit synthesis of T_4 and T_3 , leading to reduction of their serum concentrations
 - Heterocyclic compounds known as thionamides and include:
 - Methimazole, carbimazole, and propylthiouracil
 - ◻ Intrathyroidal actions: inhibition of oxidation and organification (iodination of tyrosine residues in thyroglobulin), inhibition of iodotyrosine coupling, possible alteration of structure of thyroglobulin, possible inhibition of thyroglobulin biosynthesis
 - ◻ Extrathyroidal actions: inhibition of conversion of T_4 and T_3
 - Iodine therapy (potassium iodide)
 - Major actions include:
 - ◻ Transient decrease of T_4 and T_3 synthesis by inhibiting iodine oxidation and organification
 - ◻ Block release of T_4 and T_3 from thyroid by inhibiting thyroglobulin proteolysis
 - Major uses of iodide include:
 - ◻ Preparation of patients for surgery
 - ◻ Treatment of thyrotoxic storm
 - ◻ After radioiodine therapy
 - Beta-blockers
 - Propranolol (sustained release) or long-acting beta-blockers such as metoprolol or atenolol
 - Control peripheral manifestations of disease
 - Do not result in histopathologic changes in appearance of thyroid gland

Treated Graves Disease

- Iodine treatment results in involutional changes of thyroid as a result of vascular ablation
 - Medical therapy produces no changes in histologic appearance of Graves thyroid.
- Histologic findings include:
 - Follicular epithelial cells revert to cuboidal or flat appearance.
 - Restoration of colloid
 - Papillary hyperplasia reduced but can still be seen
- With continued iodine treatment:
 - Follicular atrophy and fibrosis are seen.
 - Increased fibrosis results in prominent nodular appearance to thyroid gland.
- These changes are variably seen in treated thyroid gland so that remnants of hyperplastic-appearing thyroid can still be present even in a gland that shows treatment effects.

- Radioactive iodine:
 - Widely used in patients with thyrotoxicosis caused by Graves disease
 - Effective, safe, and relatively inexpensive
 - Initially causes cellular necrosis that provokes inflammatory response
 - Over time, chronic inflammation and fibrosis result in substantial decrease in size of thyroid gland, perhaps inevitably resulting in hypothyroidism.
- Surgery (total or near total thyroidectomy) is performed for patients:
 - Who are allergic to or noncompliant with medical therapy
 - Who are pregnant women and allergic to thionamides
 - With large goiters or severe ophthalmopathy
 - Who prefer ablative (surgical) therapy to radioiodine therapy
- Course of hyperthyroidism in Graves disease is variable:
 - Some patients have cyclic course characterized by cycles of remission and relapse of variable duration.
 - Some patients have unremitting disease course.
 - Some patients only have a single episode of disease.
- Patients treated with antithyroid drugs are more apt to achieve remission:
 - In about 10% to 15% of patients who have a remission, spontaneous hypothyroidism due to Hashimoto thyroiditis ultimately occurs (decades later).
- Thyroid cancer may develop in Graves disease:
 - Most are incidental papillary thyroid carcinomas but follicular carcinomas may develop in this setting.
 - Role of thyroid-stimulating antibodies in development of thyroid cancer suggested, but there is no evidence to support this hypothesis.
 - Thyroid cancers that occur in Graves disease may behave more aggressively.

Toxic Nodular or Multinodular Goiter (Fig. 27-67)

Definition: Presence of thyrotoxicosis (hyperthyroidism) in association with a nodular or multinodular thyroid gland.

Synonyms: Toxic adenoma; Plummer disease

- Incidence unknown
- Usually occurs in patients older than 50 years, predominantly women, who have a goiter for many years (decade or more)
 - Can occur in younger-aged individuals without gender predilection

Fig. 27-67. Toxic multinodular goiter.

^{99m}Tc pertechnetate scans show enlargement of the thyroid gland with regions of increased and decreased uptake. (From Som P, Curtin H: *Head and neck imaging*, ed 4, St Louis, 2003, Mosby.)

- Principal clinical manifestations include:
 - Cardiovascular: atrial fibrillation or tachycardia
 - Weakness and muscle wasting are common.
- Radioactive iodine uptake:
 - Show increased and decreased uptake in an enlarged gland:
 - Distinct pattern from homogeneous uptake in Graves disease
 - Overall uptake not as avid as in Graves disease
 - In toxic adenoma uptake is limited to a single nodule.
- Histomorphology:
 - Similar to diffuse toxic goiter (Graves disease), except that changes are limited to nodular foci rather than representing a diffuse process with involvement of the entire thyroid gland
 - Hyperactive nodules are usually well demarcated with discrete fibrous capsule.
 - Papillary hyperplasia consists of follicles with tall columnar cells.
 - Retrogressive changes may be present.
- Nodules are usually benign but there are rare examples of hyperfunctioning follicular carcinomas (primary or metastatic).
- Goal of therapy is to remove autonomous functioning nodule(s)
- Treatment options include:
 - Radioiodine therapy:
 - Preferred treatment

BOX 27-9 Non-Neoplastic Goitrous Lesions

- Endemic goiter
- Dyshormonogenetic goiter or inborn error of thyroid metabolism
- Amyloid goiter
- Diffuse toxic goiter (Graves disease)
- Nodular toxic goiter

- Preferred treatment for older patients who may be poor surgical candidates
- Surgery (partial or subtotal thyroidectomy)
- Antithyroid drugs
 - Induction of euthyroid state by antithyroid medication has been used prior to surgery or radioiodine therapy.
- Recurrence of toxic nodules may occur but is uncommon.

Goiters

Definition: Nonspecific term used for enlargement of thyroid gland.

- Variety of etiologies (Box 27-9)
- Use of the term goiter does not reflect functional activity.
- Presently, use of term goiter is in reference to benign (non-neoplastic) glandular enlargement (i.e., hyperplasia) of thyroid gland.
- In presence of an intact hypothalamic-pituitary axis, any deficiency of circulating thyroid hormone will cause an increase in production of thyroid stimulating hormone (TSH or thyrotropin), which leads to increased activity of thyroid follicular cells, resulting in compensatory glandular enlargement (hyperplasia):
 - Same compensatory hyperplasia will also occur in presence of circulating antibodies to thyroid follicular epithelial cells
- Most common cause of deficiency of circulating thyroid hormone is dietary deficiency of iodine (iodine-deficiency goiter):
 - Endemic goiter used when more than 10% of a given population is affected and is common in regions where nutritional iodine is insufficient or deficient
 - Sporadic (nodular) goiter most common in regions where nutritional iodine is sufficient (e.g., United States)
 - Goitrogenic factors possibly linked to the development of sporadic goiters include dietary goitrogens (cyanoglucosides, cassava [manioc], naturally occurring goitrogens in groundwater, soybeans and in specific plant genus [Brassicaceae]), goitrogenic drugs (lithium salts, iodides,

aminoglutethimide, antithyroid drugs [propylthiouracil, methimazole, perchlorate, thiocyanate]), physical agents (radiation)

- No functional or morphologic features that distinguish sporadic from endemic goiter
 - Difference between these types of goiter is that endemic goiter is most often caused by an extrathyroidal growth-stimulating factor (i.e., iodine deficiency) leading to increased TSH secretion whereas sporadically occurring goiter is not.

Adenomatoid Nodule(s)

(Figs. 27-68 through 27-78)

Definition: Diffuse enlargement(s) of thyroid gland with varying degrees of nodularity not associated with hyperthyroidism or hypothyroidism and not resulting from autoimmune thyroid disease, inflammation, or malignancy.

Synonyms: Nodular goiter; nodular hyperplasia; multinodular goiter; simple nontoxic goiter; colloid goiter

Clinical

- Most common thyroid disease:
 - Clinically detectable nodules found in 3% to 5% of population
 - If thyroid nodules found at autopsy and on histologic examination of thyroid gland are taken into consideration, then incidence increases to 40% to 50% of population.
 - Most common thyroid gland pathologic lesion encountered by surgical pathologist
- Tends to be more common in women than in men; occurs over a wide age range but predominantly seen in adult populace
- Symptoms include:
 - Patients with relatively small goiter and normal thyroid function usually asymptomatic
 - Large lesions may cause:
 - Neck discomfort
 - Dyspnea, respiratory stridor, cough, choking sensation, dysphagia, neck pain, or pressure owing to tracheal and/or esophageal displacement or compression
 - Facial disfigurement
 - Hoarseness, unilateral or bilateral vocal cord paralysis:
 - Owing to pressure on recurrent laryngeal nerve lying in close proximity
 - May be transient or permanent
 - Horner syndrome, including ptosis, miosis, and decreased facial sweating:
 - Owing to cervical sympathetic chain compression

Fig. 27-68. Nodular goiter.

Nodular goiter with dominant nodules. **A**, Axial contrast-enhanced CT scan shows marked, diffuse enlargement of the thyroid gland. There is long-standing mass effect on the trachea (*T*), posterior displacement of the left common carotid artery (*CA*), and posterolateral displacement of the left internal jugular vein (*JV*). A dominant 2.8-cm nodule is present in the isthmus of the gland (*). **B**, Axial contrast-enhanced CT scan shows diffuse enlargement of the gland with little intervening normal tissue. A second dominant nodule (*) is noted in the left lobe of the thyroid gland. Fine-needle aspiration under ultrasound guidance revealed hyperplastic nodules. (From Som and Curtin: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 41-40, page 2633.)

- Pemberton sign (see Substernal Thyroid):
 - Owing to vascular compression
- Hemorrhage in lesion may result in sudden enlargement and pain.
- Thyroid enlargement may be nodular or diffuse:
 - Isolated (single) dominant nodule may create clinical concern for a neoplasm.
 - In multinodular enlargement, there may be one or more dominant nodules.
 - No site predilection
 - Some located substernally (substernal goiter); see previous discussion in this chapter
 - Some located in lateral neck anatomically separated from main gland proper and referred to as parasitic nodule (see previous discussion in this chapter)
- Majority of patients are euthyroid:
 - Most patients have normal levels of TSH.
 - Some patients may have hyperfunctioning nodules (elevated TSH).
 - Serum thyroglobulin often elevated
 - In small percentage of patients, toxic or hyperfunctioning nodules may develop in setting of multinodular goiter:
- Thyrotoxicosis (hyperthyroidism) in multinodular goiters referred to as Plummer disease (see Toxic Nodular Goiter):
 - Tends to affect older people with long-standing goiters
 - Produces a “hot” nodule
- Radiology:
 - High-resolution ultrasound is most sensitive method of detecting thyroid nodules and may reveal small nodules that are not able to be palpated.
 - Multinodular glands appear as enlarged symmetric or asymmetric glands containing nodules of varying density.
 - Following contrast enhancement, nodules may show uniform enhancement or there may be poor enhancement due to secondary degenerative changes such as hemorrhage, cyst formation, or necrosis.
 - Areas of calcification can be seen in a high percentage of cases.
 - Large nodules may extend into mediastinum (anterior > posterior) and/or may compress adjacent structures such as the trachea, esophagus, and large vessels.

Fig. 27-69. Multinodular goiter.

A, Axial CT scan shows the lower end of a multinodular goiter extending down into the substernal space. The length of extension below the top of the manubrium should be noted in the radiology report. This goiter remained above the innominate vessels. Axial CT scan (**B**) and a sagittal reconstruction (**C**) on another patient show a large goiter extending down into the substernal region and anterior mediastinum. Notice that there is no posterior mediastinal extension or extension up behind the pharynx. (From Som and Curtin: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 41-48, page 2635.)

Fig. 27-70. Cytology of adenomatoid nodule.

Adenomatoid nodule, fine-needle aspiration biopsy. **A**, Abundant colloid with scant cluster of follicular epithelium. **B**, Benign follicular cells that are evenly spaced about the size of red blood cells (Diff-Quik stain).

Fig. 27-71. Adenomatoid nodule, fine-needle aspiration biopsy.

A, Flat sheet of follicular epithelium including cells arranged in an orderly honeycomb fashion with distinct cell borders. **B**, Another example showing benign follicular cells with round to oval monomorphic nuclei and finely granular chromatin; hemosiderin-laden macrophages (arrowheads) are present a finding seen in lesions with cystic degeneration (Papanicolaou stain).

- Radioactive iodine uptake usually normal but may be increased
- Etiology:
 - Worldwide, iron deficiency is most important factor increasing risk for development of endemic sporadic goiter
 - Prevalence inversely proportional to iodine intake
 - Direct correlation between degree of iodine deficiency and size of goiter representing physiologic adaptation to lack of iodine:
 - Decrease in blood iodine levels leads to decrease in thyroxine (T_4) levels, which in turn stimulates secretion of TSH (in effort to

Fig. 27-72. Adenomatoid nodules.

Resection specimen showing separate delineated colloid nodules with reddish to brownish, glistening appearance. Intranodular and internodular fibrosis can be seen and foci of calcifications are present.

enhance iodine uptake and restore T_4 blood levels); in turn TSH stimulates follicular cell hyperplasia and hypertrophy

- Subsequently, nodules become autonomous and secrete thyroid hormone independently of TSH due to activating mutations of thyrotropin receptor.
- Iodine excess has goitrogenic effect due to its action in decreasing synthesis and secretion of thyroid hormones.

Pathology

Fine-Needle Aspiration Biopsy

- Designation “benign follicular nodule” applies to samples adequate for evaluation consisting of:
 - Predominantly colloid
 - Benign-appearing follicular cell in varying proportions
- In presence of supporting clinical history, more specific diagnoses may be used, including:
 - Colloid nodule
 - Adenomatoid nodule
 - Hyperplastic nodule
- Secondary degenerative (retrogressive) changes may be present, including:
 - Reactive epithelial changes may include:
 - Oncocytic cytoplasm, prominent nucleoli, cytoplasmic hemosiderin
 - Hemorrhage:
 - Recent (fresh hemorrhage)
 - Remote in form of hemosiderin-laden macrophages
 - Mixed inflammatory cells:
 - Lymphocytes

Fig. 27-73. Adenomatoid nodules.

A, Three separate circumscribed but unencapsulated histologically similar-appearing nodules. **B**, Nodule with markedly dilated colloid-filled follicles. **C** and **D**, Higher magnification shows bland cytomorphic features including round to oval monomorphic nuclei with finely granular (coarse-appearing) chromatin.

Fig. 27-74. Adenomatoid nodule.

Adenomatoid nodule with retrogressive changes including cyst formation and hemorrhage.

- Foamy histiocytes, macrophages, multinucleated giant cells
- Calcific debris
- In hyperplastic lesions, follicles predominate and there is increased cellularity with scant colloid.
 - Despite increased cellularity, epithelial cells are bland, relatively uniform in appearance without significant variation in size and shape of nuclei, irregularities in size and shape, or inclusions. Nuclear grooves can be identified.
- In involuted lesions, minimal cellularity and abundant colloid may be seen.
- Features that favor an adenomatoid nodule over follicular neoplasm include presence of:
 - Abundant colloid, few follicles, and low cellularity:
 - Amount of thyroid follicles, follicular epithelial cells, and colloid are variable.

Fig. 27-75. Retrogressive changes in adenomatoid nodules.

Adenomatoid nodules with retrogressive changes may include **(A)** cyst formation and irregular fibrosis, the latter within the lesion but also enveloping the nodule(s) suggesting encapsulation; **(B)** nodule with greater cellularity but also with retrogressive changes including irregular fibrosis and foci of calcifications (*arrowhead*). The fibrosis is within the nodule as well as surrounding (enveloping) the nodule suggesting encapsulation. **(C)**, In contrast to relative uniformity in thickness and linear/parallel arrangement of fibers in a true capsule, fibrous tissue as part of retrogressive changes is irregular with thicker and thinner areas and with disorganization in arrangement of its fibers; **(D)** cyst formation and granulation tissue; **(E)** papillary architecture; **(F)** *left*, papillae in adenomatoid nodules are lined by cells with orderly arrayed small round to oval monomorphic and hyperchromatic nuclei; *right*, in contrast the nuclei in papillary carcinoma are haphazardly arrayed with crowding and overlapping nuclei that are enlarged with clear-appearing nuclear chromatin.

Fig. 27-76. Dominant adenomatoid nodule.

Adenomatoid nodules may present as a single dominant lesion (corresponding histologically to increased cellularity, see next image). This nodule appears encapsulated suggesting the gross appearance of a true neoplastic growth (adenoma or carcinoma). In this case, the patient was irradiated in childhood and this nodule was cellular with associated fibrosis.

- Follicular cells isolated or in sheets with a honeycomb pattern
- Follicular epithelial cell nuclei are round and relatively uniform in appearance with rare nucleoli and opaque to coarsely granular cytoplasm:
 - Nuclear grooves can be identified.
 - Absence of constellation of nuclear features diagnostic for papillary thyroid carcinoma
- Colloid appears as amorphous blue to orange material.

Gross

- Vary in appearance depending on number and size of nodules:
 - Generally, thyroid glands in setting of adenomatoid nodules are enlarged (slight enlargement to massive enlargement) and may achieve weights of several hundred grams to a kilogram or more.
- Cut section:
 - May reveal one or multiple delineated nodules separated by normal-appearing parenchyma
 - Nodules are reddish to brownish and have a glistening appearance.
- Secondary degenerative changes are common and may include:
 - Cyst formation, fibrosis, calcification, hemorrhage, and necrosis

Histology

- One or more nodules may be seen.
- Nodules may be:

- Circumscribed to appearing encapsulated
- Unencapsulated or partly encapsulated
- Follicles are dilated and filled with abundant colloid:
 - Some dilated follicles have a cluster of small follicles along one aspect (pole) of a follicle protruding into a dilated follicle, a finding referred to as Sanderson polster.
- Cellularity varies:
 - In some nodules cellularity is not increased and follicular epithelial cells have a flattened (attenuated) appearance.
 - Other nodules may have increased cellularity (cellular nodules) with variable appearing cells including cells with:
 - Oncocytic and/or clear cytoplasmic changes
 - Signet ring appearance
 - Spindle cell metaplasia
- Nuclei
 - Round to oval without irregularities in size and shape
 - Coarse nuclear chromatin pattern (hyperchromatic)
 - Inconspicuous to small, centrally located nucleoli
 - More or less retain linear basal orientation in cell
- In any given nodule there may be nuclear alterations raising concern for a diagnosis of papillary thyroid carcinoma including presence of:
 - Nuclear grooves
 - Dispersed or vesicular appearing chromatin
 - Crowding and overlapping
 - Intranuclear inclusions not typically identified but may be present:
 - Presence of nuclear inclusions alone not definitively diagnostic for papillary thyroid carcinoma in absence of additional diagnostic nuclear features:
 - Nuclear inclusions seen in papillary thyroid carcinoma that may be seen in other lesions appear eosinophilic with distinct margination.
 - Presence of so-called “bubble artifact,” which is a function of poor fixation, may be mistaken for intranuclear inclusions associated with papillary thyroid carcinoma.
 - “Bubble” artifact often are seen in more central and less fixed portions of lesion.
 - In contrast to intranuclear inclusions of papillary thyroid carcinoma, which have distinct margination and appear eosinophilic, bubble artifact “inclusions” show indistinct margination with clear appearance.
 - “Bubble” artifact can be present in a wide variety of thyroid lesions.

Fig. 27-77. Cellular adenomatoid nodule.

A, Irregular fibrosis that in areas envelopes the cellular lesion but also is present within the lesion as are other retrogressive changes. **B**, In this example, there is an unencapsulated cellular follicular epithelial proliferation. **C**, Microfollicular growth composed of cells with small round to oval monomorphic nuclei with coarse nuclear chromatin. **D**, Oncocytic cells may be present in adenomatoid nodules whether a component of a histologically "usual" nodule or one with increased cellularity. **E**, Signet ring cells may be present focally or representing a more significant component of the nodule. **F**, Intranuclear holes or so-called "bubble" artifact may be present and may be mistaken for intranuclear inclusions associated with papillary thyroid carcinoma; in contrast to intranuclear inclusions of papillary thyroid carcinoma, which have distinct margination and appear eosinophilic, artifactual "inclusions" have indistinct margination with clear appearance.

Fig. 27-78. Sanderson polster.

A, B, Sanderson polsters represent dilated follicle with cluster of small follicles along one aspect (pole) of follicle protruding into dilated follicle.

- Non-nodular thyroid essentially normal without hyperplastic changes:
 - Thyroid parenchyma adjacent to nodules not compressed and shows comparable growth pattern and cell type(s) as seen within nodule
- Mixed chronic inflammatory cell infiltrate including lymphocytic and plasma cell may be seen in nodule or in adjacent normal thyroid parenchyma.
- Reactive and degenerative (retrogressive) changes can be seen occurring spontaneously or secondary to a traumatic event such as prior fine-needle aspiration biopsy and may include:
 - Cyst formation
 - Papillary architecture
 - Irregular fibrosis
 - Hemorrhage (recent and remote in form of hemosiderin-laden macrophages)
 - Cholesterol granuloma formation
- Cells with oncocytic cytoplasmic changes
- Squamous metaplasia
- Calcifications:
 - Tend to be coarse and variably distributed
 - Lack concentric laminations of psammoma bodies
- Osseous and cartilaginous metaplasia may be present.
 - Thickened vascular spaces with associated calcifications (within media) can be seen at periphery.
- Reactive fibrosis versus encapsulation:
 - In any given case, there may be a dominant nodule or even multiple nodules that appear enveloped by fibrous tissue, suggesting complete encapsulation and a diagnosis of a true follicular neoplasm.
 - In contrast to relative uniformity in thickness and linear/parallel arrangement of fibers in a true capsule, fibrous tissue surrounding one or more adenomatoid nodules is:
 - Irregular with thicker and thinner areas and shows disorganization in arrangement of fibers
 - Present within as well as around lesion
 - Such findings support presence of reactive fibrosis and should allow for differentiating from a follicular adenoma.
 - Often such irregular fibrosis is accompanied by other retrogressive findings (see above), allowing for consideration and diagnosis of adenomatoid nodule.
 - In presence of irregular fibrosis coupled to tangential sectioning lesional tissue may appear separate from main lesion identified in fibrous tissue within as well as around lesion raising concern for presence of capsular invasion and a possible diagnosis of follicular carcinoma:
 - In such settings, quality of fibrosis (irregular and disorganized), location of fibrosis (within and around lesion), presence of additional retrogressive changes, as well as overall histology of lesion including cellularity and similar cytomorphology to cells in surrounding parenchyma should allow for diagnosis of adenomatoid nodule and discrimination from follicular carcinoma.
- Endocrine atypia:
 - Endocrine atypia includes cells with nuclear hyperchromasia and marked nuclear pleomorphism.
 - Usually focal but may be multifocal or more widespread
 - Absence of associated mitotic activity or necrosis
 - Felt to represent benign reactive process (e.g., post-fine-needle aspiration biopsy)

- Not an indicator of malignancy
- Can be seen in non-neoplastic proliferations (e.g., dyshormonogenetic goiter, others) and in follicular adenoma
- Atypical nuclear features in adenomatoid nodules:
 - Occasionally, an otherwise nondescript nodule may show isolated focus or separate small foci without evidence of invasive growth in which nuclear characteristics are those of papillary thyroid carcinoma, follicular variant.
 - In such examples, diagnostic possibilities may include:
 - Entire nodular lesion represents papillary thyroid carcinoma:
 - This is an example in which lesion appears to be an adenomatoid nodule, but in fact entire lesion represents papillary thyroid carcinoma, follicular variant.
 - Focus or foci of papillary thyroid carcinoma represent(s) cancer developing in setting of adenomatoid nodule(s).
 - Focus or foci of papillary thyroid carcinoma represent(s) intrathyroidal/intranodular spread from separate focus of papillary thyroid carcinoma located elsewhere in gland.
 - Of note is wide discrepancy and lack of consensus among pathologists in evaluation/determination of diagnostic nuclear features for papillary thyroid carcinoma and diagnostic “handling” of such cases remains problematic and to a large extent subjective
 - To date, no consensus how to diagnostically handle such cases as described above:
 - Some authorities use varying terms, including:
 - Adenomatoid nodule with atypical features
 - Atypical follicular lesion neoplasm of uncertain malignant potential
 - Some authorities render a diagnosis of microscopic focus/foci of papillary thyroid carcinoma arising in adenomatoid nodule(s).
 - No established quantitative measurement (e.g., percentage of given lesion) in trying to decide when lesion does or does not represent papillary thyroid carcinoma:
 - If significant percentage (too many areas in single or multiple slides) of lesion shows nuclear features diagnostic for papillary thyroid carcinoma, then designation of entire lesion as papillary thyroid carcinoma, follicular variant would appear justified.
 - If there are insufficient findings to render a diagnosis of papillary thyroid carcinoma, a conservative diagnostic approach (i.e., benign lesion) appears justified, given indolent biology associated with such lesions lacking invasive growth:
 - Many such lesions may fall within potential histologic spectrum of so-called follicular variant of papillary thyroid carcinoma that:
 - In absence of invasion essentially behaves as a benign neoplasm (i.e., follicular adenoma) with minimal to no risk of metastatic disease and/or death from tumor
 - Have molecular biologic findings identical to those of follicular adenoma (and follicular carcinoma) including presence of *RAS* mutation and absence of *RET/PTC* and *BRAF*
 - For more details see Follicular Variant of Papillary Thyroid Carcinoma, including the recent recommendation to replace this diagnostic designation with noninvasive follicular tumor [NIFT] with papillary-like features.
 - A view that entire nodule represents papillary thyroid carcinoma does not alter prognosis as the lesion is noninvasive, amenable to surgical resection, and associated with an excellent prognosis; however, therapeutic implications include fact that any such lesion measuring more than 1 cm and diagnosed as papillary thyroid carcinoma would prompt surgical removal of all remaining thyroid tissue (i.e., completion thyroidectomy) and adjuvant radioactive iodine therapy. With recommended change in nomenclature to noninvasive follicular tumor with papillary-like features, conservative management (e.g., lobectomy without radioactive iodine therapy) should be advocated.
 - Cytogenetics and molecular genetics:
 - Initial studies showed adenomatoid nodules to be polyclonal.
 - Subsequent studies have shown that at least some adenomatoid nodules are monoclonal with cytogenetic abnormalities, aneuploidy, and oncogenic mutations to support a neoplastic origin.
 - Such findings complicate differentiation of non-neoplastic (dominant) adenomatoid nodule from neoplastic follicular adenoma.

Differential Diagnosis

- Follicular adenoma (Table 27-2):
 - Differentiation essentially based on arbitrary findings, including:
 - Adenoma:
 - Single lesion
 - Completely encapsulated
 - Dissimilar cytomorphology to surrounding parenchyma
 - Compression of surrounding parenchyma

TABLE 27-2 Adenomatoid Nodules Versus Follicular Adenoma

Feature	Adenomatoid Nodules	Follicular Adenoma
Number	Multiple	Solitary
Capsule	Poor encapsulation; a capsule may be present but it does not completely encapsulate mass; in association with retrogressive changes fibrosis may envelop lesion but appears irregular of variable thickness, including marked thickening within and around lesion(s)	Well-developed, completely surrounding mass; appears rather uniform in thickness and appearance
Adjacent thyroid gland	No compression of surrounding gland	Compression of surrounding gland
Growth as compared to rest of the thyroid gland	Comparable growth pattern in adjacent gland	Different growth pattern in adjacent gland
Appearance as compared with the rest of the thyroid gland	Variable cellularity similar to those outside nodules	Uniform cellularity dissimilar to remainder of gland
Degenerative changes	Frequently present	May be present but not common
Clonality	Polyclonal cell population; studies have shown that at least some adenomatoid nodules are monoclonal with cytogenetic abnormalities, aneuploidy and oncogenic mutations to support a neoplastic origin	Monoclonal cell population

TABLE 27-3 Adenomatoid Nodules Versus Papillary Thyroid Carcinoma

Features	Adenomatoid Nodules	Papillary Carcinoma
Papillae	Simple	Complex
Nuclei	<ol style="list-style-type: none"> 1. Round and regular 2. Dense chromatin (hyperchromatic) 3. Linear polarity along basal aspect of cell 4. Nuclei are not crowded or overlap 5. Nuclear grooves and “inclusions” may be present 	<ol style="list-style-type: none"> 1. Enlarged with irregularities in size and shape 2. Dispersed to optically clear chromatin pattern 3. Disorganized orientation of nuclei without linear polarity of the nuclei, which are haphazardly located within the cells 4. Nuclear crowding and overlapping 5. Nuclear grooves 6. Intranuclear inclusions
Fibrosis	Variable and irregular in appearance; may be markedly thickened in and around the follicles	Intratumoral, irregular in appearance and more dense (fibromatosis-like)
Calcifications	Dense deposits lacking any specific form (i.e., lamination or concentric rings) usually in fibrotic (acellular) foci and within the media of vessels	Laminated or having concentric rings (psammoma bodies) and seen in association with the neoplastic cellular infiltrate and in the connective tissue of the parenchyma

- Adenomatoid nodules:
 - Multiple lesions
 - Lack of capsule or complete encapsulation
 - Similar cytomorphology to surrounding parenchyma
 - No compression of surrounding parenchyma
- In any given case distinction between adenomatoid nodule (dominant or multiple) from adenoma (multiple albeit uncommon) or arising in setting of adenomatoid nodules can be problematic.
- From practical standpoint this differentiation is between benign lesions so that therapy and prognosis are essentially similar.
- Follicular carcinoma:
 - See Histology above.
- Papillary thyroid carcinoma, conventional type, and follicular variant (Table 27-3)

Treatment and Prognosis

- Patients with asymptomatic nontoxic goiter(s) do not need to undergo any therapy:
 - Management with periodic serum TSH measurement and ultrasound assessment considered reasonable
- Surgery is preferred treatment for symptomatic nodules:
 - Surgery should be as conservative as possible, including resection of mass lesion(s) with sparing of the remaining thyroid.

- Total thyroidectomy may be required in those patients with:
 - Multifocal, bilateral nodules
 - Large intrathoracic lesions causing moderate or severe compressive symptoms
 - For large lesions with low radioactive iodine uptake that usually require extremely high radioactive iodine therapy for successful treatment
- Thyroid hormone replacement initiated after total or near total thyroidectomy
- Radioiodine therapy (^{131}I therapy) can be used for ablation of adenomatoid nodules:
 - Option for patients:
 - With contraindications for surgery (e.g., advanced age with associated comorbidities)
 - Who reject surgery
 - Who have had prior surgery or radiation to neck, making surgical procedures more difficult
 - Nodules are relatively radioresistant and higher doses are required in treating adenomatoid nodules.
 - Larger nodules require higher radioiodine dose for ablation.
 - Risks associated with this form of treatment may include radiation exposure of entire thyroid with possible:
 - Increase risk of developing cancer
 - Hypothyroidism
- Prognosis in uncomplicated cases is excellent.
- No increased risk of developing cancer in setting of adenomatoid nodules

Dyshormonogenetic Goiter (DG)

(Figs. 27-79 through 27-81)

Definition: Inherited or inborn errors of thyroid metabolism resulting in overstimulation (hyperplasia) of thyroid gland.

- Numerous causes of inborn errors of thyroid metabolism (Box 27-10), all of which result in a deficient amount of circulating thyroid hormone, which leads to a loss in negative feedback to pituitary gland which, in turn, leads to hypersecretion of thyroid-stimulating hormone (TSH) causing continuous stimulation and hyperactivity of thyroid gland

Clinical

- Rare:
 - 1 in 30,000 to 50,000 live births
- Too few cases to make any definitive statements regarding mode of inheritance but appears that autosomal recessive inheritance is much greater than autosomal dominant inheritance

Fig. 27-79. Dyshormonogenetic goiter.

Total thyroidectomy specimen showing an enlarged thyroid gland with nodules and degenerative changes, including cyst formation, fibrosis, and hemorrhage.

BOX 27-10 Inherited Metabolic Disorders of Thyroid Metabolism Resulting in Dyshormonogenetic Goiter

- Unresponsiveness to thyroid-stimulating hormone (TSH)
 - Iodide transport failure
 - Defective peroxidase activity
 - Deficient hydrogen peroxide activity:
 - Receptor abnormality
 - Iodide organification or Pendred syndrome (familial deaf-mutism and goiter)
 - Defective iodotyrosyl coupling and iodothyronine synthesis
 - Defective thyroglobulin:
 - Impaired synthesis (absence or synthesis of abnormal thyroglobulin)
 - Defective transport
 - Defective iodotyrosine
 - Other:
 - Nodular goiter with intense thyroid calcification
 - Familial absence of the thyroid gland (athyreosis)
-
- More common in women than in men; occurs over wide age range from neonates to sixth decade with median of 16 years of age:
 - Most cases develop prior to third decade.
 - No racial or ethnic predilection
 - Thyroid abnormalities seen in disorders of thyroid hormonogenesis include:
 - Goitrous thyroid and hypothyroidism
 - Pituitary gland defects result in hypothyroidism but not a goiter
 - Clinical presentation (signs and symptoms) dependent on severity of the error:
 - Severe defect:
 - Presentation in early life (neonatal period) with (congenital) hypothyroidism, goiter, mental

Fig. 27-80. Dyshormonogenetic goiter.

A, Diffusely hyperplastic thyroid including the presence of papillary hyperplasia with minimal to absent colloid and increased cellularity. **B**, Multiple nodules characterized by increased cellularity with decreased to absent colloid. In both illustrations there is an absence of histologically normal thyroid parenchyma as well as an absence of an associated lymphocytic cell infiltrate.

retardation, and growth abnormalities (cretinism)

- Mild or less severe defect:
 - Presentation in adolescence or adult life with goiter and minimal evidence of thyroid dysfunction; patients may be euthyroid
- Extrathyroid malformations may be present, including:
 - Urogenital malformations
 - Cardiac abnormalities on echocardiography
 - Features of dysmorphism in form of high-arched palate, low-set ears, and microcephaly
- Laboratory evaluation for patient suspected of having an inborn error of thyroid metabolism is complex and extensive and follows a sequential flowchart depending on findings of any one or more test results.

- Among tests that may be performed and evaluated for thyroid dyshormonogenesis include:
 - T_4 and T_3 concentration
 - Thyroid-stimulating hormone (TSH)
 - Thyroxine-binding globulin (TBG)
 - Thyrotropin releasing hormone (TRH): assessment of hypothalamic-pituitary function
 - Radioiodine uptake and scanning
 - Thyroglobulin antibodies (if present, the patient may have an autoimmune thyroiditis)
 - Hearing test:
 - Sensorineural deafness in presence of goiter and hypothyroidism diagnostic of Pendred syndrome
 - Origin for congenital nerve deafness unknown
 - Radioiodine kinetic studies for labeled urinary monoiodotyrosine (MIT) and diiodotyrosine (DIT):
 - Defective iodotyrosine deiodination characterized by release of MIT and DIT in degradation of thyroglobulin in process of recovery of its thyroid hormones
 - Surgical excision for histologic analysis
- Diagnosis of an inborn error of thyroid metabolism can be made in utero by ultrasonography and the measurement of TSH in amniotic fluid.
- Most cases of thyroid dysgenesis are sporadic and of unknown cause:
 - There may be a family history of goiter.

Pathology

NOTE: Irrespective of underlying cause, pathologic changes (gross and microscopic) seen are essentially the same.

Gross

- Enlarged thyroid gland that in some cases may weigh up to 600 g
- Glands are (multi)nodular with associated fibrosis, which may encapsulate individual nodules.
- In addition to fibrosis, other secondary (degenerative) changes may include:
 - Cyst formation, hemorrhage, and, less commonly, calcification

Histology

- Diffuse process with absence of any normal appearing thyroid tissue
- Thyroid is characterized by nodularity, fibrosis, and marked follicular hyperplasia with prominent papillarity (simple not complex), hypercellularity, and decreased to absent colloid.
 - Microfollicular, trabecular, macrofollicular, solid, and microcystic growth patterns can be seen.

Fig. 27-81. Dyshormonogenetic goiter.

Dyshormonogenetic goiter is characterized by **(A)** papillary hyperplasia and absence of colloid; **(B)** variably dilated follicles including micro- and macrofollicles devoid of colloid; **(C)** follicular growth including identifiable colloid-filled follicles but other follicles without colloid; **(D)** nodular appearance with nodules separated by fibrosis and minimal to absent colloid formation. Note the variegated cytomorphology in figures **C** and **D**, including cells with relatively bland nuclei and other areas in which there is nuclear pleomorphism; **(E)** severe cytologic atypia, including hypercellularity with marked nucleomegaly, hyperchromasia, and intranuclear inclusions.

- In any one gland, all of above features can be present, creating a variegated appearance at low magnification.
- Follicular epithelial cells of nodules include cells with round to oval nuclei, coarse nuclear chromatin pattern, eosinophilic to clear cytoplasm, and basal orientation of nuclei within the cell.
- Marked cytologic atypia in internodular thyroid tissue commonly present, including:
 - Bizarre nuclei with nucleomegaly and hyperchromasia
 - Mitotic activity and/or necrosis not present
- Fibrosis consisting of thick, acellular bands seen throughout gland
 - Fibrosis may completely encircle (“encapsulate”) the nodules.
 - Presence of nodules surrounded by fibrosis may suggest a follicular neoplasm (adenoma or carcinoma).
 - Fact that entire thyroid gland is histologically abnormal may assist in diagnosis and in differentiating from follicular adenoma or carcinoma
- Despite presence of prominent papillarity, nuclear features do not conform to those seen in papillary thyroid carcinoma.
- A benign lymphocytic cell infiltrate may be present.
- Myxoid change may be present.
- Malignant thyroid tumors (papillary thyroid carcinoma or follicular carcinoma) may develop in setting of dys hormonogenetic goiter; features that may assist in diagnosis include:
 - For papillary thyroid carcinoma:
 - Characteristic architectural and/or cytomorphic features, including complex (not simple) papillary growth, elongated or twisted appearing follicles, enlarged nuclei with irregularities in size and shape, dispersed to optically clear-appearing nuclear chromatin, margination of the chromatin along nuclear membrane, crowding and overlapping nuclei, loss of basal polarity of nuclei, nuclear grooves, and nuclear (eosinophilic) inclusions
 - For follicular carcinoma:
 - Somewhat more problematic in “encapsulated” nodules of dys hormonogenetic goiter may appear to have foci of “invasive” growth into capsule
 - Presence of angioinvasion and/or metastasis would be diagnostic of follicular carcinoma.
 - No definitive cytologic features that can be used in differentiating dys hormonogenetic goiter from follicular carcinoma
- Histochemistry:
 - Periodic acid-Schiff (PAS) can be used to identify colloid in cases with areas in which colloid production is minimal to absent.

- Immunohistochemistry:
 - Thyroglobulin and TTF-1 reactivity
 - Absence of calcitonin or neuroendocrine markers (e.g., chromogranin, synaptophysin)

Differential Diagnosis (Table 27-4)

- Diffuse hyperplasia (Graves disease)
- Adenomatoid nodules
- Papillary thyroid carcinoma
- Follicular thyroid carcinoma
- Medullary thyroid carcinoma

Treatment and Prognosis

- Surgery (partial or total thyroidectomy) may be necessary for patients with obstructive or pressure symptoms, or in those patients suspected of having a malignant neoplasm.
- Nonsurgical (medical) treatment is same as that for any hypothyroid patient and includes thyroid hormone replacement:
 - Intra-amniotic injections of thyroxine in fetus with fetal goiter detected by routine ultrasound in early pregnancy (gestational week 18) and fetal hypothyroidism (TSH >100 mU/l) suspected of having DG reported to have beneficial effects as evidenced by reduction in growth of goiter was reduced and reduction of elevated amniotic TSH levels over course of pregnancy
- Due to generalized pituitary insufficiency, patients may develop adrenal crisis if unmonitored medical treatment is given.
- Prognosis especially for those patients with mild disease is excellent.
- In patients with severe forms of disease (congenital goiters and cretinism), mental and growth retardation may occur.
 - In these patients, early detection with early medical management is essential for normal development of nervous system and in preventing permanent mental retardation.

Amyloid Goiter (Figs. 27-82 and 27-83)

Definition: Symptomatic mass or clinically detectable thyroid enlargement due to amyloid deposition.

- Amyloid deposits represent extracellular accumulation of fibrillar proteins, which are identified in association with a variety of clinical settings and occurring in a variety of tissue sites.
- Amyloidosis may manifest in several forms, including:
 - Systemic amyloidosis (primary and secondary)
 - Multiple myeloma-associated amyloidosis
 - Localized or solitary amyloidosis
 - Familial amyloidosis

TABLE 27-4 Dyshormonogenetic Goiter and Histologic Simulators

	Dyshormonogenetic Goiter	Graves Disease (Untreated)	Papillary Carcinoma (Classic Type)	Adenomatoid Nodules (Nodular Goiter)
Gland involvement	Diffuse; thyroid is hyperplastic; no normal thyroid; increased nodularity	Diffuse; thyroid is hyperplastic; no normal thyroid	Limited in extent; multifocal; intervening thyroid tissue is normal	Multiple nodules; intervening thyroid tissue is normal
Cellularity	Hypercellular throughout the gland	Hypercellular throughout the gland	Variable cellularity but typically more cellular than surrounding thyroid	Variably cellular from hypo- to hypercellular
Architecture	Microfollicular, trabecular, macrofollicular, solid and microcystic with prominent papillarity; papillae are present throughout the gland; papillae are usually simple in appearance but may be complex, are often broad rather than narrow, and have a fibrovascular stroma	Diffuse follicular hyperplasia; prominent papillary architecture; lobular architecture retained; papillae are present, typically are simple in appearance but may be complex, and are often broad rather than narrow, with a fibrovascular stroma	Multiple growth patterns: papillary, follicular (micro- and macrofollicular), solid, trabecular; papillary growth limited to neoplastic proliferation; narrow papillae have a complex growth with fibrovascular stroma	Variable-sized follicles widely dilated; retrogressive changes may include the presence of papillae
Colloid	Scant to absent	Minimal to absent; scalloping is present	Present; darker (inspissated) appearing	Abundant; watery in appearance
Cytomorphology (follicular epithelial cells)	Variably appearing epithelial cells with round to oval nuclei, coarse chromatin, eosinophilic to clear cytoplasm; basal orientation of the nuclei; severe cytologic atypia is commonly present and includes bizarre nuclei with nucleomegaly and hyperchromasia in parenchyma and less often in nodules	Columnar cells; enlarged nuclei, amphophilic cytoplasm, indistinct cell borders; nuclei are round and regular with coarse chromatin arranged along the basal aspect of the cell	Enlarged nuclei; irregularities in size and shape; haphazardly located in cell; dispersed to optically clear chromatin; nuclear crowding and overlapping; nuclear grooves and intranuclear round and eosinophilic inclusions; nondescript cytoplasm	Flattened cells, round and regular nuclei with a dense chromatin; nuclei are linearly oriented along basal aspect of cell; nuclear grooves; "inclusions" may be present, appearing clear and bubbly, and are artifacts of tissue processing
Fibrosis	Marked fibrosis; fibrosis accentuates nodularity	Minimal to absent fibrosis in the untreated patient or in a patient without long-standing disease; when present, fibrosis is irregular and often creates a nodular appearing gland	Intratumoral; dense irregular bands	Variable and irregular in appearance; result of retrogressive changes

Clinical

- Very rare occurrence
 - Most common setting in which amyloid is seen occurs in the thyroid is in association with medullary thyroid carcinoma.
- Amyloid deposition in thyroid can occur as part of both primary and secondary systemic amyloidosis:
 - More commonly seen as part of secondary systemic amyloidosis:
 - In this setting, amyloid is usually found at autopsy rather than resulting in symptomatic mass.
- Predisposing disorders associated with secondary systemic amyloidosis involving thyroid include:
 - Chronic inflammatory diseases: infections (chronic osteomyelitis, pulmonary tuberculosis, chronic bronchitis with bronchiectasis, chronic peritonitis), rheumatoid arthritis, familial Mediterranean fever
 - Neoplasms including Hodgkin disease, others
- In symptomatic amyloid goiter, clinical presentation includes nontender, rapidly enlarging neck mass that may be associated with dysphagia, dyspnea, and hoarseness.

Fig. 27-82. Amyloid goiter.

The amyloid deposition is eosinophilic, acellular, and amorphous in appearance and almost completely replaces the thyroid parenchyma. Elongated thyroid follicles lined by attenuated follicular epithelial cells are seen, one of which still retains colloid material (*left of center*).

Fig. 27-83. Amyloid goiter.

Left panel, Light microscopic appearance of amyloid including deposition of acellular and amorphous eosinophilic material surrounding a colloid-filled follicle. *Right panel*, Congo red stain showing characteristic apple-green birefringence.

- Patients are euthyroid and thyroid dysfunction is not generally present, however:
 - Amyloid deposition may be so extensive as to result in hypothyroidism.
 - May rarely be associated with hyperthyroidism

Pathology

Fine-Needle Aspiration Biopsy

- Aspirated material contains few cells and small fragments of cyanophilic material (amyloid).
- Amyloid is congophilic.

Gross

- Enlarged glands with nodular to diffuse appearance weighing from 25 to 300 g
- Cut surface is white to tan with a rubbery to firm consistency.

Histology

- Diffuse amyloid deposition is usually seen but focal (nodular) deposits may occur.
- Amyloid appears as extracellular eosinophilic, acellular, and amorphous material.
- In diffuse deposition, amyloid is evenly distributed throughout gland replacing thyroid parenchyma.
- In nodular deposition, amyloid is focally seen and remainder of gland is essentially unremarkable.
- Degree of amyloid deposition may vary from moderate to extensive.
- Amyloid is seen in perifollicular and interfollicular locations compressing follicles.
- In areas of amyloid deposition, residual follicles vary in appearance from elongated with normal colloid content to slit-like atrophic follicles without colloid.
 - Follicular epithelial cells generally appear as flat single cells.
 - Squamous metaplasia may be seen.
- Amyloid deposition seen around vascular spaces (“angiocentric”) and, less often, within walls of vascular spaces:
 - Vascular-related amyloid does not result in any functional compromise of involved vascular space.
- Additional associated findings may include:
 - Chronic lymphocytic thyroiditis
 - Foreign body type giant cell reaction
 - Areas of mature fat
- Histochemistry:
 - Stains for amyloid (Congo red, crystal violet, thioflavin-T) are positive:
 - Apple-green birefringence seen under polarized light with Congo red staining
- Immunohistochemistry:
 - Positive reactivity with amyloid A (AA) antibody
 - Calcitonin and chromogranin reactivity are not seen.
- Electron microscopy:
 - Nonbranching fibrils varying in size from 50 to 150 Å in diameter

Differential Diagnosis

- Amyloid stroma in medullary thyroid carcinoma
- Amyloid may be mistaken for fibrous tissue; latter may be seen in association with many thyroid diseases.

Treatment and Prognosis

- Treatment in symptomatic patients is thyroidectomy (partial or total).
- Prognosis in relationship to amyloid deposition of thyroid gland is excellent:
 - However, patient deaths may occur due to specific organ failure secondary to amyloid deposition (cardiac, renal, or hepatic).
- Prognosis in relationship to amyloid deposition occurring in the setting of medullary thyroid carcinoma correlates to that associated with medullary thyroid carcinoma (see Chapter 28).

Neoplasms of the Thyroid Gland

CLASSIFICATION OF NEOPLASMS OF THE THYROID GLAND

See [Box 28-1](#).

BOX 28-1 Classification of Thyroid Gland Neoplasms

Follicular Epithelial Origin

Benign

- Follicular adenoma and variants

Malignant

- Follicular carcinoma and variants
- Papillary carcinoma and variants
- Poorly differentiated carcinoma
- Undifferentiated (anaplastic) carcinoma
- Others:
 - Squamous cell carcinoma
 - Mucoepidermoid carcinoma
 - Tumors with thymic-like differentiation

C-Cell Origin

- Medullary thyroid carcinoma

Mixed Follicular and C-Cell Origin

- Mixed medullary and follicular carcinoma
- Mixed medullary and papillary carcinoma

Nonepithelial Tumors

Benign

- Paraganglioma
- Teratoma

• Mesenchymal tumors:

- Benign peripheral nerve sheath tumor
- Granular cell tumor
- Hemangioma
- Leiomyoma
- Solitary fibrous tumor
- Others

Malignant

• Malignant lymphoproliferative lesions:

- Non-Hodgkin malignant lymphoma
- Plasmacytoma
- Hodgkin lymphoma
- Others

• Sarcomas:

- Angiosarcoma
- Follicular dendritic cell sarcoma
- Leiomyosarcoma
- Others

Secondary Tumors

GENERAL CONSIDERATIONS

- Thyroid cancer is the most common endocrine malignancy but represents 1.4% to 4.6% of all new human cancers diagnosed in the United States.
- Incidence of thyroid carcinoma in United States has increased rapidly since 1980:
 - More refined/sophisticated detection methods including radiologic imaging (ultrasound, CT, MRI) contribute to increase in incidence.
 - Sharpest increase is in diagnosis of papillary thyroid carcinoma, particularly papillary microcarcinoma but also follicular variant of papillary thyroid carcinoma.
- Percentage of cancer deaths (mortality rate) due to thyroid cancer is low (less than 0.4% in women and in men):
 - In contrast to increase in incidence, changes in mortality rates have been much smaller, likely resulting from:
 - Improved treatment
 - Increased incidence primarily in early stage papillary carcinoma
- Clinically apparent thyroid nodules occur in fairly large percentage of the population (up to 10%):
 - Many of these nodules are probably benign.
 - Differential diagnosis of any thyroid nodule includes a malignant thyroid neoplasm.
- Demographics:
 - In general, thyroid tumors are more common in women than in men and occur in all ages ranging from the young (children in the first and second decades of life) to elderly adults.
- Risk factors for development of thyroid cancer include:
 - Radiation exposure:
 - Causes thyroid carcinoma primarily by direct effects on DNA
 - Primarily associated with external radiation

- Internal (^{131}I) radiation therapy used safely for diagnostic and therapeutic purposes associated with small increase risk of thyroid carcinoma incidence
 - Risk factors associated with radiation-induced thyroid tumors include:
 - Amount of radiation exposure
 - Young age at exposure to radiation
 - High serum thyroglobulin levels
 - Genetic predisposition:
 - Only 5% of follicular cell-derived thyroid carcinomas are a component of a familial cancer syndrome.
 - Familial follicular cell-derived tumors or non-medullary thyroid carcinoma encompass a heterogeneous group of diseases classified into two distinct groups:
 - Syndromic-associated tumors occur in syndromes in which nonmedullary thyroid carcinomas are predominant tumor encountered, including:
 - Phosphatase and tensin (PTEN)-hamartoma tumor syndrome/Cowden syndrome
 - Familial adenomatous polyposis/Gardner syndrome
 - Carney complex type 1, Werner syndrome, Pendred syndrome
 - Other syndromes, such as McCune-Albright syndrome, Peutz-Jeghers syndrome, and ataxia-telangiectasia syndrome, may be associated with development of follicular cell-derived tumors but link is less established than above syndromes.
 - Nonsyndromic tumors occur in tumor syndromes in which thyroid involvement is minor component, including:
 - Familial follicular cell-derived tumor syndromes or nonsyndromic tumors:
 - Non-medullary thyroid carcinomas are major findings, including:
 - Pure familial papillary thyroid carcinoma with or without oncocytic cytoplasmic change; familial papillary thyroid carcinoma with papillary renal cell carcinoma; familial papillary thyroid carcinoma with multinodular goiter; familial nonmedullary (papillary) thyroid carcinoma type 1
 - Familial adenomatous polyposis (FAP) syndrome, including its subtype Gardner syndrome:
 - Autosomal dominant inheritance with mutations in *APC* gene (5q21)
 - Characterized by multiple adenomatous polyps of the large intestine, multiple osteomas of the skull and mandible, cutaneous keratinous cysts, and soft tissue tumors (e.g., fibromatosis)
- Associated with an increased risk of papillary thyroid carcinoma (PTC):
 - Thyroid carcinoma occurs in up to 12% of patients
 - Tend to occur at early age
 - Histologically, include PTC, cribriform-morular variant, and solid variant
- Phosphatase and tensin homolog (PTEN)-hamartoma tumor syndrome, including Cowden disease (multiple hamartoma syndrome):
 - Autosomal dominant inheritance
 - Germline mutation of *PTEN* gene (10q23.2)
 - Characterized by multiple hamartomas, mucocutaneous lesions, including trichilemmomas, acral keratoses, and oral mucosal papillomas
 - Associated with increased risk of follicular epithelial cell lesions/tumors, including:
 - Adenomatoid nodules accounting for 75% of thyroid abnormalities in this setting
 - PTC and follicular carcinomas may also occur.
- Other familial disorders with specific gene mutations associated with thyroid carcinoma include:
 - Carney complex:
 - Germline mutation *PRKR1 α* (17q22-24)
 - Follicular carcinoma and papillary carcinoma
 - Werner syndrome:
 - Germline mutation *WRN* (8p11-22)
 - Follicular carcinoma, papillary carcinoma, undifferentiated (anaplastic) thyroid carcinoma
 - Pendred syndrome
 - Mutation of Pendred syndrome (*PDS*) gene (*SLC26A4* gene on chromosome 7q31) encodes amino acid protein pendrin shown to function as iodide/chloride transporter
 - Goitrous thyroid
- Familial nonmedullary thyroid carcinoma (FNMTc):
 - Originate from follicular cells of thyroid gland accounting for more than 90% of all thyroid cancers
 - Approximately 3% to 10% of FNMTcs are of familial origin defined as two or more affected first-degree relatives with NMTC in the absence of other known familial syndromes.
 - Greater than 85% of thyroid tumors in non-syndromic FNMTc are papillary thyroid carcinoma followed by follicular thyroid carcinoma (approximately 10%); poorly differentiated and undifferentiated (anaplastic) thyroid carcinomas represent approximately 5%.

- Compared to sporadic NMTC, FNMTC:
 - Presents at younger age
 - Associated with higher incidence of multifocal disease, extrathyroidal extension, and nodal metastasis
 - Multiple endocrine neoplasia syndrome:
 - Linked to development of C-cell-related lesions/neoplasms
 - See Section 10.
- Dietary factors:
 - Iodine:
 - In iodine-deficient diets (endemic goiter areas), follicular thyroid carcinoma more common
 - In iodine-sufficient diets, papillary thyroid carcinoma more common
- Pre-existing thyroid diseases:
 - Thyroid carcinoma often preceded by other thyroid abnormalities, including:
 - Adenomatoid nodules
 - Lymphocytic thyroiditis
 - Graves disease
 - Remains uncertain whether patients with above abnormalities are at increased risk for developing thyroid carcinoma
- Hormonal and reproductive factors:
 - Thyroid carcinoma occurs more commonly in women than in men.
 - Differences between genders in thyroid cancer incidence declines with age.
 - Increasing parity may increase risk of thyroid carcinoma.
 - Thyroid carcinoma reported to occur more often among women who are older when they first give birth.
 - Small increase in risk of thyroid carcinoma with increasing age at menopause
 - Other suggested risk factors for thyroid carcinoma in women are:
 - Exogenous estrogens, including oral contraceptives
 - Lactation-suppressant drugs
 - Postmenopausal estrogen therapy
 - Fertility drugs (e.g., clomiphene, progesterone)
- Clinical findings:
 - Most patients with benign thyroid nodules/tumor and carcinomas present with asymptomatic thyroid nodule.
 - Clinical findings related to risk of carcinoma in thyroid nodule include:
 - Age:
 - Overall most patients with thyroid carcinoma are middle age.
 - Thyroid nodule is more likely to be carcinoma in patients under 20 years and in patients over 65 years of age.
 - Gender:
 - Men are more apt to have malignant thyroid tumors than women.
 - Family history of thyroid cancer or syndrome associated with thyroid cancer
 - History of childhood head and neck therapeutic irradiation, total body irradiation, or exposure to ionizing radiation
 - History of other cancer:
 - Kidney, breast, lung, and melanoma
 - Sudden or rapid enlargement of thyroid or of long-standing thyroid nodule(s) with or without pain:
 - Most likely represents hemorrhage into a cystic nodule:
 - Occurs in benign and malignant nodules
 - Hallmark presentation for some thyroid malignant tumors, including undifferentiated (anaplastic) carcinoma and malignant lymphoma
 - Large nodule with distortion of structures of upper neck and mediastinum and/or tracheal compression with difficulty breathing:
 - Can occur in association with benign thyroid nodules but presence of these symptoms raises concern for a malignant thyroid lesion, although most malignant thyroid tumors are asymptomatic
 - Hoarseness and/or vocal cord paralysis:
 - Most commonly related to laryngeal-based disease (benign or malignant) but can be associated with infiltration of recurrent laryngeal nerve by thyroid cancer
- Physical examination:
 - Number of nodules:
 - Although not always true, multiple nodules more likely to be benign, whereas solitary nodules more likely to be malignant
 - Hard and fixed thyroid mass:
 - More likely to be malignant
 - Ipsilateral cervical adenopathy:
 - May indicate metastasis from an (ipsilateral) thyroid malignant tumor clinically overt or occult
- Laboratory testing:
 - Most patients with thyroid cancer are euthyroid.
 - Serum thyroglobulin:
 - Often elevated in patients with papillary and follicular carcinoma:
 - May be elevated in association with follicular adenoma so does not necessarily allow for distinguishing benign and malignant thyroid follicular neoplasms.
 - Not typically elevated in medullary thyroid carcinoma and undifferentiated (anaplastic) thyroid carcinoma

- Useful in monitoring patients following treatment (surgery and radioactive iodine) for papillary or follicular carcinoma as elevated levels may indicate recurrence or metastasis.
- Serum calcitonin:
 - Elevated levels represent diagnostic feature that may occur in medullary thyroid carcinoma
- Germline RET proto-oncogene mutation testing:
 - Indicated in patients with thyroid nodule and family history of medullary thyroid carcinoma or potential diagnosis of multiple endocrine neoplasia (MEN) type II syndrome
- Radiologic imaging:
 - Ultrasonography:
 - Thyroid ultrasound used in patients with palpable nodules (with or without elevated TSH) to:
 - Determine presence of single discrete nodule or multiple nodules
 - Demonstrate anatomic location of nodule in thyroid (anterior versus posterior) as well as composition (cystic versus solid)
 - Assess nodule(s) size
 - Thyroid malignancies tend to:
 - Be hypoechogenic (particularly marked hypoechogenicity)
 - Be solid
 - Have infiltrative or microlobulated margins
 - Show presence of microcalcifications
 - Be taller than wide shaped when measured in transverse view
 - However, no single feature or combination of sonographic features is sufficiently sensitive to be the sole screening test for thyroid cancer.
 - Thyroid nodule may be considered benign when:
 - Purely cystic
 - Spongiform appearing (>50% of nodule volume occupied by microcystic spaces)
 - On basis of thyroid sonographic imaging features, nodule appearance can be classified as:
 - Low risk for malignancy:
 - Tend to be purely cystic or spongiform
 - Noninfiltrative borders
 - Intermediate risk for malignancy:
 - Predominantly solid, hypo- or iso- to hyperechoic
 - Noncalcified
 - Regular margins
 - High risk for malignancy:
 - Hypoechoic
 - Microcalcifications
 - Infiltrative or microlobulated margins
 - Radionuclide imaging
 - Thyroid scintigraphy using ^{123}I or $^{99\text{m}}\text{Tc}$ pertechnetate
 - Incidence of carcinoma higher for hypofunctioning “cold” nodules than for hyperfunctioning (“hot”) nodules
 - “Hot” nodules are almost always benign
- Fine-needle aspiration biopsy (FNAB)
 - Represents an extremely useful initial approach in diagnosis of thyroid mass
 - Quick and inexpensive with minimal complications
 - Thyroid nodules are one of most common indications for neck FNAB.
 - Presurgical diagnosis via FNAB prevents unneeded surgery for benign, nonprogressive lesions and helps to triage patients with a neoplasm for appropriate procedure.
 - Diagnostic sensitivity and specificity reported to be high, greater than 90%
 - Standardization and interpretation of thyroid cytology greatly improved by widespread adoption of Bethesda reporting system (Table 28-1), which classifies biopsies in six-tiered system as well as including implied risk of malignancy and associated usual management (Table 28-2)
 - Post-FNAB histologic changes may create diagnostic problems in the evaluation of tissue sections, including presence of features raising concern for malignancy, including:
 - Pseudoinvasion, necrosis, papillary architecture, cytologic atypia
 - See Chapter 29.
- Intraoperative consultation (frozen section diagnosis):
 - Use of intraoperative frozen sections in diagnosis of thyroid tumors has decreased with increasing use of FNAB.
 - See Chapter 29.
- Histologic types of thyroid neoplasms:
 - Majority of thyroid tumors are of follicular epithelial cell origin and include:
 - Follicular adenoma and variants thereof
 - Follicular carcinoma and variants thereof
 - Papillary carcinoma and variants thereof
 - Less common are C-cell-derived medullary thyroid carcinoma
 - Nonepithelial neoplasms of thyroid are uncommon:
 - Most common nonepithelial thyroid neoplasm is malignant lymphoma.
 - Rarely, primary mesenchymal tumors as well as metastases to thyroid gland occur.
 - Frequency of malignant thyroid neoplasms include:
 - Papillary carcinoma: approximately 80% to 85%
 - Follicular carcinoma: approximately 10% to 15%

TABLE 28-1 Bethesda System for Reporting of Thyroid Cytopathology: Diagnostic Categories

Category	Diagnoses	Findings	Frequency of Diagnosis
I	Nondiagnostic or unsatisfactory	Cyst fluid only; virtually acellular specimen; other (obscuring blood, clotting artifact, etc.)	<15%
II	Benign	c/w: • Benign follicular nodule (e.g., ANs) • CLT • Granulomatous (subacute) thyroiditis	30% to 75%
III	Atypia of undetermined significance or follicular lesion of undetermined significance	Contain cells with architectural and/or nuclear atypia not sufficient to be classified as suspicious for follicular neoplasm, suspicious for malignancy, or malignant but show atypia more marked than benign lesions	<10%
IV	Follicular neoplasm or suspicious for follicular neoplasm	Specify if oncocyctic (Hürthle) cell type	~5%
V	Suspicious for malignancy	Suspicious for: PTC; MTC; metastatic carcinoma; lymphoma	<5%
VI	Malignant	PTC; PDTC; MTC; UC; SCC; carcinoma with mixed features; metastatic carcinoma; NHL	~5%

~, Approximately; c/w, consistent with; ANs, adenomatoid nodules; CLT, chronic lymphocytic (Hashimoto) thyroiditis; MTC, medullary thyroid carcinoma; NHL, non-Hodgkin lymphoma; PDTC, poorly differentiated thyroid carcinoma; PTC, papillary thyroid carcinoma; SCC, squamous cell carcinoma; UC, undifferentiated (anaplastic) carcinoma.

From Ali SZ, Cibas EA, editors: *The Bethesda system for reporting thyroid cytopathology: definitions, criteria and explanatory notes*, New York, 2010, Springer.

TABLE 28-2 Bethesda System for Reporting of Thyroid Cytopathology: Risk of Malignancy and Recommended Clinical Management

Bethesda Classification	Risk of Malignancy	Recommended Management
Nondiagnostic or unsatisfactory (Bethesda I)	N/A	Repeat FNA with ultrasound guidance
Benign (Bethesda II)	0 to 3%	Clinical follow-up
Atypia of undetermined significance, follicular lesion of uncertain significance (Bethesda III)	5% to 15%	Repeat FNA
Follicular neoplasm, suspicious for follicular neoplasm (Bethesda IV)	15% to 30%	Surgical lobectomy
Suspicious for malignancy (Bethesda V)	60% to 75%	Near total thyroidectomy or surgical lobectomy
Malignant (Bethesda VI)	>95%	Near total thyroidectomy

From Ali SZ, Cibas EA, editors: *The Bethesda system for reporting thyroid cytopathology: definitions, criteria and explanatory notes*, New York, 2010, Springer.

- Medullary carcinoma: <5%
- Poorly differentiated thyroid carcinoma: <2%
- Undifferentiated (anaplastic) thyroid carcinoma: <2%
- Malignant lymphoma: <5%
- Immunohistochemistry of thyroid neoplasms
 - Majority of thyroid cancers are differentiated carcinomas of follicular epithelial cell origin diagnosed on morphologic grounds.
 - Immunohistochemical staining can be important and at times essential in confirming specific diagnosis.
 - Table 28-3 includes an overview of more common antibodies that may be used in diagnosis of the more common thyroid neoplasms.
- Molecular genetics of thyroid tumors (Table 28-4):
 - Papillary thyroid carcinomas have activating mutations of genes coding for proteins, which signal along the mitogen-activated protein kinase pathway (MAPK).
 - Papillary thyroid carcinomas commonly have three genetic alterations, including:
 - RET/PTC rearrangements
 - BRAF point mutations
 - RAS point mutations
 - Mutations in RET, BRAF, and RAS genes found in approximately 70% of all papillary thyroid carcinomas but rarely overlap in same tumor
 - RET (rearranged during transfection) protooncogene:

TABLE 28-3 Antibodies Used in Diagnosis of Thyroid Neoplasia

Antibody	FA	FTC	PTC	MTC	UTC	PDTC
Thyroglobulin	+	+	+	–	–	+*
TTF-1 (N)	+	+	+	+	–	+
PAX8 (N)	+	+	+	+	+	+
Calcitonin	–	–	–	+	–	–
NE markers	–	–	–	+	–	–
CD56	+	+	R/A	+	–	–
CK (AE1/AE3)	+	+	+	+	±	+

CK, Cytokeratin; FA, follicular adenoma; FTC, follicular thyroid carcinoma; N, nuclear; NE markers, synaptophysin and chromogranin; PDTC, poorly differentiated thyroid carcinoma; PTC, papillary thyroid carcinoma; R/A, reduced to absent; TTF-1, thyroid transcription factor 1; UTC, undifferentiated thyroid carcinoma.

*Typically very focal limited to abortive or small follicles containing colloid or limited to isolated cells as paranuclear globules or vacuoles.

TABLE 28-4 Common Genetic Alterations in Thyroid Neoplasia

Tumor Type	Affected Genes	Prevalence
Follicular adenoma	<i>RAS</i> <i>PAX8/PPARγ</i> translocation	20% to 40% 5% to 20%
Follicular carcinoma	<i>RAS</i> <i>PAX8/PPARγ</i> translocation <i>PIK3CA</i> mutation <i>PTEN</i>	30% to 50% 20% to 50% 5% to 10% 5% to 10%
Papillary carcinoma, classical	<i>BRAF</i> <i>RET/PTC</i> translocation <i>RAS</i> <i>TRK</i>	30% to 70% 20% to 40% 0 to 10% 0 to 10%
Papillary carcinoma, follicular variant	<i>RAS</i> <i>PAX8/PPARγ</i> translocation <i>RET/PTC</i> translocation <i>BRAF</i>	25% to 45% 0 to 30% 5% to 10% 5% to 10%
Poorly differentiated carcinoma	<i>RAS</i> <i>TP53</i> <i>B-catenin</i> (CTNNB1) <i>BRAF</i> <i>PIK3CA</i> mutation <i>AKT1</i> mutation	20% to 50% 15% to 40% 0 to 25% 5% to 15% 10% to 20% 5% to 10%
Undifferentiated (anaplastic) carcinoma	<i>TP53</i> <i>B-catenin</i> (CTNNB1) <i>RAS</i> <i>BRAF</i> <i>PIK3CA</i> mutation <i>PTEN</i> mutation	50% to 80% 5% to 65% 10% to 50% 10% to 40% 5% to 25% 5% to 20%
Medullary carcinoma Sporadic Familial	<i>RET</i> , somatic <i>RET</i> , germline mutation	50% >95%

- Rearrangements of *RET* gene, known as *RET/PTC* rearrangements, occur in papillary thyroid carcinoma (PTC).
- *RET/PTC* rearrangement implicated in early stages of PTC representing early event in development of PTC
- Several types of *RET/PTC* identified differing according to 5' partner gene involved in rearrangement
 - Two most common rearrangement types are:
 - *RET/PTC1*: typically found in classic PTC, papillary microcarcinomas
 - *RET/PTC3*: more common than the other fusion proteins in solid and radiation-induced PTCs, especially in children exposed to the radiation fallout from the Chernobyl accident
- Uncommon to rare in follicular variant of PTC
- Germline mutations present in virtually all patients with familial forms of medullary thyroid carcinoma, including:
 - MEN-2A
 - MEN-2B
 - Familial medullary thyroid carcinoma
- Somatic mutations of *RET* codon 918 occur in approximately 50% of sporadic medullary thyroid carcinomas.
- B-RAF proto-oncogene, serine/threonine kinase (*BRAF*) mutation:
 - Belongs to RAF family of protein kinases important components of the mitogen-activated protein kinase (MAPK) signaling pathway mediating cell growth, differentiation, and survival
 - Spectrum of mutations include point mutations, small in-frame deletions or insertions, and chromosomal rearrangement.
 - V600E is most common mutation (98% to 99%) and involves nucleotide 1799, resulting in valine-to-glutamate substitution at residue 600 (V600E).
 - Mutations of *BRAF* gene found in 40% to 45% of PTCs
 - Occur early in development of PTC based on presence in papillary microcarcinomas
 - Among thyroid tumors *BRAF* mutations restricted to:
 - Papillary thyroid carcinoma:
 - Classic type
 - Papillary microcarcinomas
 - Tall cell variant
 - Poorly differentiated thyroid carcinomas
 - Undifferentiated (anaplastic) thyroid carcinoma arising from thyroid papillary carcinoma.

- Uncommon to rare in follicular variant of PTC
- Not found in follicular carcinoma and benign thyroid nodules
- Reported to serve as prognostic marker for PTC associated with more aggressive features including:
 - Tumor recurrence
 - Extrathyroidal extension
 - Metastatic disease (regional, distant)
 - Advanced tumor stage (AJCC III/IV)
- Purported aggressive behavior of *BRAF*-associated PTCs not universally reported
- Rat sarcoma (*RAS*) oncogene mutations:
 - Found in benign and malignant thyroid neoplasms, suggesting *RAS* activation may be an early step in thyroid tumor development
 - 3 *RAS* genes prominent in cancer pathogenesis, including:
 - Neuroblastoma *RAS* viral oncogene homolog (*N-RAS*)
 - Kirsten rat sarcoma viral oncogene homolog (*K-RAS*)
 - Harvey rat sarcoma viral oncogene homolog (*H-RAS*)
 - Found in all types of follicular cell-derived tumors:
 - Prevalence includes *N-RAS* > *H-RAS* > *K-RAS*
 - *RAS* mutations found in:
 - 40% to 50% follicular carcinomas:
 - Lower incidence of oncocytic variant
 - 20% to 40% follicular adenomas:
 - Lower incidence of oncocytic variant
 - 10% to 20% PTCs:
 - Virtually all follicular variants of PTC
 - Also found in 20% to 50% of poorly differentiated thyroid carcinoma and 10% to 50% of undifferentiated (anaplastic) thyroid carcinoma
- Other molecular genetic findings in thyroid neoplasms:
 - Peroxisome proliferator-activated receptor γ (*PAX8/PPAR γ*) gene rearrangement:
 - Nuclear receptors that bind DNA as heterodimers with retinoid X receptors
 - Shown to play important role in regulating genes involved in adipocytic differentiation and lipid metabolism
 - Result in recurrent translocation t(2;3)(q13;p25) leading to fusion of thyroid transcription factor *PAX8* and *PPAR γ* genes
 - *PAX8/PPAR γ* rearrangements involved in thyroid cancer found in:
 - 20% to 50% of conventional FTC: ~5% of oncocytic carcinomas
 - 5% to 20% of follicular adenomas
 - 1% to 5% follicular variant of PTC
 - 0 to 1% of classic PTC
 - Thyroid tumors with *PAX8/PPAR γ* rearrangement do not usually carry any *RAS* mutation, suggesting that the development of FTC involves two independent pathways associated with either *PAX8/PPAR γ* translocation or *RAS* mutation
 - Tend to be present in:
 - Younger-age patients
 - Smaller tumors
 - Tumors more likely to be angioinvasive
- Telomerase reverse transcriptase (*TERT*) gene mutations:
 - Telomeres are the terminal portion of chromosomes that protect chromosome integrity by preventing their degradation and uncontrolled fusion and breaking cycles with other chromosomes
 - Telomerase (telomere terminal transferase) is an RNA-dependent reverse transcriptase complex that maintains telomere length allowing for cell replication and extending the life span of the cell
 - *TERT* is the enzyme protein core encoded by the *TERT* gene and is expressed in thyroid tumors (but is not normally expressed in thyroid tissue).
 - Found in 12% of papillary thyroid cancers and 14% of follicular thyroid cancers
 - Found to significantly correlate with older age at diagnosis
 - Demonstrated in thyroid cancers particularly prevalent in aggressive, less differentiated thyroid cancers, including:
 - Tall cell variant-PTC, poorly differentiated thyroid cancer, undifferentiated (anaplastic) thyroid cancer, and *BRAF* V600E mutation-positive PTC
 - Shown to strongly correlate with poorer outcome in differentiated thyroid tumors
 - Prognostic value of *TERT* mutations reported to be significantly stronger than that of *BRAF* (V600E)
 - *TERT* protein by immunohistochemical staining found to be more expressed in neoplastic than in normal tissues and to display different cellular localization, suggesting it could contribute to thyroid cancer progression by mechanisms taking place in cytoplasm
- Phosphatidylinositol 3-kinase (PI3K)/AKT (AKT) signaling pathway
 - Plays important role in regulation of cell survival, proliferation, and migration

- Activating mutations in *RAS*, *PIK3CA*, and *AKT* genes or inactivating mutations in *PTEN* tumor suppressor gene can inappropriately stimulate signaling pathway.
- Mutations in signaling pathway occurs in:
 - 5% to 10% of (differentiated) follicular carcinomas
 - More common in poorly differentiated thyroid carcinoma and undifferentiated (anaplastic) thyroid carcinoma harboring: *PIK3CA* mutation (10% to 20%) and *AKT1* mutation (5% to 10%)
 - *PIK3CA* and *AKT1* mutations frequently present in undifferentiated (anaplastic) thyroid carcinoma coexisting with *BRAF* and *RAS* mutations
- Late event in thyroid carcinogenesis:
 - Higher prevalence in advanced thyroid cancer and undifferentiated (anaplastic) thyroid carcinoma
- β -catenin:
 - Ubiquitously expressed cytoplasmic protein
 - Inappropriate stabilization followed by nuclear translocation proposed as important step in oncogenesis
 - *CTNNB1* gene encodes β -catenin
 - Somatic mutations in exon 3 reported in:
 - 25% of poorly differentiated thyroid carcinoma
 - 60% of undifferentiated (anaplastic) thyroid carcinoma
 - Rare in (well) differentiated thyroid cancers
 - Oncogenic signaling through β -catenin occurs in the cribriform morular variant of PTC in the setting of familial adenomatous polyposis with germline *APC* mutations and in sporadic cases.
- Tumor protein 53 (TP53) tumor suppressor gene
 - Most commonly mutated tumor suppressor gene in human cancer
 - Transcriptional activator involved in cell cycle progression:
 - Ability to arrest cell cycle and activate program cell death confers significant to TP53 in determining cell survival
 - Inactivating point mutations of TP53 tumor suppressor gene highly prevalent in poorly differentiated thyroid carcinoma and undifferentiated (anaplastic) thyroid carcinoma
 - Not present in (well) differentiated thyroid cancers
 - Represent late event in progression and dedifferentiation of thyroid cancer
- Micro-RNAs (miRNAs or miRs):
 - Belong to class of small noncoding messenger RNA that have emerged as potent regulators of a variety of biologic processes, including oncogenesis
 - Act as posttranscriptional regulators of gene expression and are constantly deregulated in human cancer; found downregulated in lung, colon, and prostate cancer
 - Increasingly implicated in regulating malignant progression of cancer
 - Involved in thyroid cell proliferation and migration validating role in downregulation in thyroid carcinogenesis
 - MiR-221 and miR-222 found to be deregulated in human papillary thyroid carcinomas; involved in cell proliferation through inhibition of cell cycle regulator, p27kip1, in human papillary carcinomas
 - miRs may regulate fundamental aspects of the PTC phenotype, i.e., signaling, differentiation, invasion and metastasis, by fine tuning gene expression
 - Increased role in determining thyroid cancer phenotype serving as important diagnostic tool and useful as class identifiers especially in context of follicular thyroid carcinoma, papillary thyroid carcinoma, and anaplastic thyroid carcinoma
 - Cancer-relevant miRs include oncomiRs (miR-21 and miR-146b) and tumor suppressor miRs (let-7 family, miR-204, and miR-375).
 - Increased expression of miR-21 associated with known aggressive form of PTC (tall cell variant) and may be a critical event in pathogenesis
 - OncomiRs miR-221 and miR-222 reported to play role in PTC aggressiveness; associated with less differentiated tumors
 - miRNAs and their target genes could be targeted for novel therapeutics
- Molecular classification
 - The Cancer Genome Atlas (TCGA) project:
 - Comprehensive multiplatform analysis of nearly 500 PTCs (excluding clinically aggressive thyroid cancers including poorly and undifferentiated carcinomas)
 - Integrated genomic characterization of papillary thyroid carcinoma (PTC)
 - Refine classification of PTC into molecular subtypes and associate them with clinically relevant parameters
 - PTC is MAPK-driven cancer that has two mutually exclusive drivers with distinct signaling consequences, including:

- *BRAF* V600E-like tumors include classic PTC with papillary architecture and characteristic nuclear features (whether invasive or noninvasive); gene expression profile shows relatively less evidence of thyroid differentiation with lower expression levels of thyroid differentiation scores (TDS) genes; used for all infiltrative lesions despite follicular architecture that may predominate
 - *RAS*-like tumors include encapsulated or circumscribed (noninvasive) tumors with follicular architecture and nuclear atypia (hallmarks characteristic of follicular variant of PTC); gene expression profile that resembles normal thyroid (high TDS scores); genetics similar to follicular adenoma and follicular carcinoma (not part of the TCGA project analysis).
- Reclassification of follicular variant (FV) of PTC is inevitable with recent recommended by panel of expert thyroid pathologists to replace FVPTC with alternative nomenclature such as “Noninvasive follicular tumor [NIFT] with papillary-like features.” See later under FVPTC.
- Treatment for thyroid cancer:
 - Surgery is preferred treatment for vast majority of thyroid tumors:
 - Extent of surgery varies to include:
 - Lumpectomy:
 - Removal of a nodule/mass alone with minimal surrounding thyroid tissue
 - Generally not recommended for removal of thyroid tumors
 - Partial thyroidectomy:
 - Removal of nodule/mass with larger margin of surrounding thyroid tissue
 - Unacceptable in management of thyroid cancer
 - Isthmusectomy:
 - Removal of tumor within isthmus to include a margin of surrounding thyroid tissue
 - Lobectomy or hemithyroidectomy:
 - Removal of thyroid lobe with or without isthmus
 - Subtotal thyroidectomy:
 - Complete resection of one lobe and isthmus and partial removal of contralateral lobe
 - Bilateral subtotal thyroidectomy:
 - Significant portion of both lobes removed
 - Near total thyroidectomy:
 - Removal of all thyroid tissue except for 1 gram remnant on one side typically preserved to protect adjacent parathyroid tissue or to avoid distal recurrent laryngeal nerve dissection; such a remnant must be anodular and away from cancer focus
 - Total thyroidectomy:
 - Removal of entire thyroid gland; advantages of total thyroidectomy include association with higher survival rate for larger lesions (greater than 1.5 cm); association with lowest recurrence rate; improved sensitivity of serum thyroglobulin as marker for persistent or recurrent disease; allows for utilization of radioactive iodine to treat persistent or recurrent disease; reduction in (unlikely) possibility of residual tumor in contralateral lobe transforming to an anaplastic carcinoma
 - Surgical complications may include:
 - Recurrent laryngeal nerve paralysis
 - In hands of expert thyroid surgeon risk is low (e.g., 1% to 2%)
 - Risk increases (e.g., 6% to 8%) in nonexpert thyroid surgeons
 - Hypoparathyroidism:
 - May be a significant problem in patients following bilateral or total thyroidectomy
 - Rates of temporary hypoparathyroidism (calcium levels <8.0 mg/dl within 6 months after thyroidectomy) reported to be 17% to 40%
 - Rates of permanent hypoparathyroidism range from 1.2% to 6.5%.
 - Risk of hypoparathyroidism increases with invasive cancers; when lymph node dissection is performed with thyroidectomy; linked to experience of surgeon
 - Lymph node dissection:
 - Cervical lymph nodes divided into levels I through VI and grouped into central and lateral compartments
 - See Section 4 for more detailed discussion of anatomy of cervical neck lymph nodes.
 - Surgical treatment of cervical lymph nodes in thyroid carcinoma remains subject of debate:
 - Node dissection indicated when there are palpable nodes and/or radiographically suspicious or positive lymph nodes
 - Selective neck dissection designed to remove regional lymph nodes involved by tumor or at risk for metastasis
 - Central compartment neck dissection includes tissue from hyoid bone to mediastinum and from one jugular vein to the other jugular vein:
 - Lateral deep jugular area is carefully examined (palpated) for disease.
 - In presence of palpable lymph nodes laterally lymphadenectomy to include levels II, III, IV is performed.

- Further, evaluation of the lymph nodes accompanying the inferior thyroid artery into the posterior triangle of the neck is indicated in the presence of palpable nodes, dissection of level V nodes is performed.
- Submandibular triangle usually is not included in the dissection because thyroid cancer rarely metastasizes to the submandibular triangle.
- In presence of cervical nodal metastasis and in patients with aggressive disease, imaging to include the parapharyngeal space and base of skull is indicated; because standard neck dissections do not allow for dissection of lymph nodes in these areas, if significant adenopathy of these regions is visualized, then appropriate techniques for nodal dissection of these sites should be planned and performed in addition to the standard cervical node dissection.
- Radioactive iodine therapy (^{131}I):
 - Thyroid ablation with ^{131}I used in treatment of differentiated thyroid carcinoma:
 - ^{131}I destroys residual microscopic (metastatic) thyroid cancer.
 - Facilitates identification of metastatic foci by radioactive iodine scanning
 - Used in treatment of distant metastasis with best results seen in patients who are under 40 years of age at time of their metastasis and whose metastatic foci concentrate ^{131}I
 - Poorer outcomes seen in patients over 40 years of age at time of their metastasis, have extensive metastatic disease, poorly differentiated tumors, and/or tumors that do not take up ^{131}I
 - Utility of radioactive iodine therapy is negated in presence of a normally situated thyroid gland proper because the latter would concentrate radioactive iodine rather than the planned intent for this therapy to destroy residual cancer outside the confines of thyroid gland proper.
 - Reasonably safe procedure
 - Potential complications may include:
 - Usually involve organs known to concentrate iodine, including salivary glands causing sialadenitis, loss or change in taste, xerostomia; eyes causing xerophthalmia, epiphora; gonads causing transient reductions in fertility; serious life-threatening complications are rare but may include acute bone marrow failure, reduced pulmonary function, second primary malignancy (e.g., leukemia, solid tumors)
- External irradiation:
 - May be used postoperatively in patients with differentiated thyroid carcinoma with or without metastasis
- Chemotherapy:
 - Generally has limited role in treatment of thyroid cancers; most often used in conjunction with other modes of therapy (surgery and radiation) in treatment of poorly differentiated or undifferentiated (anaplastic) carcinomas
- Thyroid hormone therapy:
 - Differentiated thyroid carcinomas contain functional thyroid stimulating hormone (TSH) receptors that are more abundant in follicular carcinoma than papillary carcinoma.
 - TSH stimulates growth of differentiated thyroid carcinoma.
 - In theory, suppression of TSH receptors with suppressive doses of thyroxine may result in tumor regression.
- Prognosis:
 - Prognosis with more common types of thyroid cancers is good with best overall survival rates associated with papillary carcinoma.
 - Important prognostic factors include:
 - Presence or absence of extrathyroidal extension
 - Presence or absence of metastatic disease: in lymph nodes, presence or absence of extranodal extension
 - Age and gender of patient
 - Pathologic features including histology, tumor size, presence or absence of encapsulation
- Follow-up:
 - There is no standard protocol in follow-up of patients with thyroid cancer.
 - In general, scintiscan should be done within 3 months following initial therapy with reexamination at 1 year.
 - Disease-free patients then have whole-body radioactive iodine scans at 3 and 5 years.
 - Recurrent tumor is treated with radioactive iodine.
 - Serum thyroglobulin measurement
 - Reliable biomarker for well-differentiated thyroid follicular epithelial cell-derived cancer recurrence
 - Specific and sensitive marker
 - Shown to have poor accuracy for predicting malignancy in follicular neoplasms with oncocytic cells
 - Serum calcitonin measurement:
 - Used to follow patients with residual or metastatic medullary thyroid carcinoma

TABLE 28-5 TNM Classification of Thyroid Carcinomas

Primary Tumor (T)	
<i>Note:</i> all categories may be subdivided: (s) solitary tumor and (m) multifocal tumor (the largest determines the classification).	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 2 cm or less in greatest dimension limited to thyroid
T1a	Tumor 1 cm or less, limited to the thyroid
T1b	Tumor more than 1 cm but not more than 2 cm in greatest dimension, limited to the thyroid
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension, limited to the thyroid
T3	Tumor more than 4 cm in greatest dimension limited to the thyroid or any tumor with minimal extrathyroid extension (e.g., extension to sternothyroid muscle or perithyroid soft tissues)
T4a	Moderately advanced disease Tumor of any size extending beyond the thyroid capsule to invade subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve
T4b	Very advanced disease Tumor invades prevertebral fascia or encases carotid artery or mediastinal vessels
All anaplastic carcinomas are considered T4 tumors.	
T4a	Intrathyroidal anaplastic carcinoma
T4b	Extrathyroidal anaplastic carcinoma with gross extrathyroid extension
Regional Lymph Nodes (N)	
Regional lymph nodes are the central compartment, lateral cervical, and upper mediastinal lymph nodes.	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
N1a	Metastasis to level VI (pretracheal, paratracheal, and prelaryngeal/Delphian lymph nodes)
N1b	Metastasis to unilateral, bilateral, or contralateral cervical (Levels I, II, III, IV, or V) or retropharyngeal or superior mediastinal lymph node (Level VII)
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

From Edge SB, et al: *AJCC cancer staging manual*, ed 7, New York, 2010, Springer, p 89.

Pathologic staging (p): Correspond to the T (pT), N (pN), and M (pM) categories.

Residual tumor is designated as R: *RX*, Residual tumor cannot be assessed; *R0*, no residual tumor, *R1*, microscopic residual tumor, *R2*, macroscopic residual tumor.

Additional descriptors: “m” suffix indicates the presence of multiple primary tumors in a single site [pT(m)NM]; “r” prefix indicates recurrent tumor when staged after a disease-free interval [rTNM]; “a” prefix indicates stage determined at autopsy [aTNM].

CLINICAL STAGING OF THYROID CARCINOMA

- Clinical staging of thyroid tumors is determined by physical examination, thyroid imaging, or endoscopic examination:
 - Inspection and palpation of thyroid gland and cervical neck
 - Imaging studies include radioisotope thyroid scans, ultrasonography, CT scan, MRI scan.
 - Endoscopic evaluation includes indirect laryngoscopy to evaluate vocal cord motion.
- TNM classification of thyroid gland cancers (Table 28-5) must include all information obtained in clinical staging plus patient demographics (i.e., age and gender) and information gathered on pathologic evaluation (i.e., fine-needle aspiration biopsy, gross and microscopic evaluation) including:
 - Cancer type (e.g., papillary or follicular carcinoma versus medullary carcinoma versus undifferentiated [anaplastic] carcinoma)

TABLE 28-6 Clinical Staging

Separate stage groupings are recommended for papillary or follicular (differentiated), medullary, and undifferentiated (anaplastic) carcinoma.				Medullary Carcinoma (All Age Groups)			
Papillary or Follicular (Differentiated)				Stage I	T1	N0	M0
<i>Under 45 years</i>				Stage II	T2	N0	M0
					T3	N0	M0
Stage I	Any T	Any N	M0	Stage III	T1	N1a	M0
Stage II	Any T	Any N	M1		T2	N1a	M0
<i>45 Years and Older</i>					T3	N1a	M0
Stage I	T1	N0	M0	Stage IVA	T4a	N0	M0
Stage II	T2	N0	M0		T4a	N1a	M0
Stage III	T3	N0	M0		T1	N1b	M0
	T1	N1a	M0		T2	N1b	M0
	T2	N1a	M0		T3	N1b	M0
	T3	N1a	M0		T4a	N1b	M0
Stage IVA	T4a	N0	M0	Stage IVB	T4b	Any N	M0
	T4a	N1a	M0	Stage IVC	Any T	Any N	M1
	T1	N1b	M0	Anaplastic Carcinoma			
	T2	N1b	M0	All anaplastic carcinomas are considered Stage IV.			
	T3	N1b	M0	Stage IVA	T4a	Any N	M0
	T4a	N1b	M0	Stage IVB	T4b	Any N	M0
Stage IVB	T4b	Any N	M0	Stage IVC	Any T	Any N	M1
Stage IVC	Any T	Any N	M1				

From Edge SB, et al: *AJCC cancer staging manual*, ed 7, New York, 2010, Springer, pp 87-88.

- Primary tumor size (T)
- Regional lymph node involvement (N)
- Distant metastasis (M)

NOTE: Pathologic staging (p): correspond to the T (pT), N (pN), and M (pM) categories

- Clinical staging of thyroid gland cancers, including papillary or follicular carcinoma, medullary carcinoma, and undifferentiated (anaplastic) carcinoma is detailed in [Table 28-6](#).

BENIGN FOLLICULAR EPITHELIAL NEOPLASMS

FOLLICULAR ADENOMA (FA) (Figs. 28-1 through 28-6)

Definition: Benign encapsulated tumor with evidence of follicular cell differentiation showing growth pattern and cytomorphology different from surrounding thyroid parenchyma, but lacking features of papillary thyroid carcinoma.

- Whether clonality is a part of definition of an adenoma in contrast to adenomatoid nodules is controversial because clonality has been shown to be present in a large percentage (70%) of dominant adenomatoid nodules in setting of nodular goiter.

Clinical

- Affects women more than men; occurs over a wide age range but is most common in the fifth to sixth decades of life

- Clinical presentation is usually that of a painless neck (thyroid) mass; duration of symptoms varies from months to years.
- Most often solitary and limited to one part of the thyroid lobe but may involve the entire lobe:
 - Uncommonly, multiple adenomas may be present in a single gland.
- Patients are usually euthyroid; serum thyroglobulin may be raised but clinical evidence of hyperthyroidism is rarely seen.
- Radiology:
 - Thyroid imaging (^{123}I or $^{99\text{m}}\text{technetium}$):
 - Most often “cold” or hypofunctional or poorly functional nodule
 - May be hyperfunctioning (“hot”) nodule:
 - Tend to be more cellular than hypofunctioning (“cold”) adenoma

Fig. 28-1. Fine-needle aspiration biopsy (FNAB), follicular adenoma.

A, Smears of follicular neoplasm are typically much more cellular than adenomatoid nodules and have a preponderance of small follicular structures. Colloid is scanty or absent in more cellular follicular neoplasms (Diff-Quik stain). **B**, Syncytial grouping of the cells in this small follicle with extruded fragment of dense colloid. The opaque chromatin pattern and round nuclear contours are typical of a follicular proliferation and contrast to features seen in association with papillary thyroid carcinoma (Papanicolaou stain). The FNAB diagnosis was “follicular neoplasm or suspicious for a follicular neoplasm (Bethesda IV).” A lobectomy was performed and the lesion proved to be a follicular adenoma.

- Sometimes associated with hyperthyroidism (toxic or Plummer adenoma)
- No specific etiologic factors associated with development of FA

Pathologic Features

Fine-Needle Aspiration Biopsy

- Often FNAB diagnosis is “follicular neoplasm, suspicious for follicular neoplasm (Bethesda IV),” which informs treating physician that a neoplasm is present requiring surgical removal (e.g., lobectomy)

Fig. 28-2. Follicular adenomas.

A, Follicular adenoma appearing as a solitary, circumscribed to thinly encapsulated lesion with tan-brown and glistening appearance. **B**, Follicular adenoma with post-FNAB retrogressive changes including necrosis, hemorrhage, and cyst formation.

- Features associated with a follicular neoplasm that contrast with those of a (cellular) adenomatoid nodule or other lesions include:
 - Syncytial groups with or without distinct microfollicles; microfollicular or trabecular growth
 - Cellular smears
 - Increased cellularity
 - Scanty colloid, which is usually dense and in follicular lumina
 - Uniform cells with round nuclei, inconspicuous nucleoli, and ill-defined cell borders
 - Nuclear chromatin is opaque to coarsely granular and usually evenly distributed
 - Cytoplasmic features vary from scant to oxyphilic.
 - Absence of nuclear features diagnostic for papillary thyroid carcinoma

Gross

- Solitary encapsulated mass:
 - Capsule varies in thickness but usually is thin.
 - Generally completely envelops tumor

Fig. 28-3. Follicular adenoma.

The hallmark of a follicular adenoma is its encapsulation and absence of invasive growth and/or nuclear features diagnostic for papillary thyroid carcinoma. The presence of a complete capsule encircling the tumor is a feature that separates an adenoma from an adenomatoid nodule. The capsule may vary from **(A)** thin to **(B)** moderately thick to **(C)** thick.

D through **F**, In all instances, the capsule appears relatively uniform in thickness with linear/parallel arrangement of fibers lacking thicker and thinner areas and disorganization in arrangement of its fibers as might be seen in reactive fibrosis. The non-neoplastic thyroid tissue adjacent to the tumor is compressed (*arrowheads* in **D** and **E**).

Fig. 28-4. Follicular adenoma.

Growth patterns may include (A) normocellular, (B) microfollicular, (C) solid, (D) organoid/insular, and (E) trabecular. The lesional cells are composed of round to oval nuclei with coarse nuclear chromatin and smooth nuclear contours. F, Rarely, intranuclear inclusions (*arrowhead*) typically associated with papillary thyroid carcinoma can be seen in other thyroid lesion types including follicular adenomas. In D through F, the cells show granular eosinophilic cytoplasm but not as brightly eosinophilic as seen in oncocyctic cells.

Fig. 28-5. Follicular adenoma, immunohistochemical staining.

Immunohistochemical staining in follicular adenomas include reactivity for **(A)** thyroglobulin, **(B)** TTF-1 (nuclear), **(C)** PAX8 (nuclear), and **(D)** CD56 (membranous).

- Vary in size but generally measure <3 cm; larger tumors measuring more than 10 cm can be seen
- Pale tan to brown to orange (oncocytic)
- Solid with a rubbery to firm consistency and a homogeneous appearance except in the presence of retrogressive changes, which may include:
 - Hemorrhage, fibrosis, cyst formation, calcification, and infarction

Histology

- Encapsulated tumors without evidence of capsular and/or vascular invasion:
 - Generally fibrous capsule completely envelops tumor
 - Capsule is composed of fibrous tissue, within which small to medium-size vascular spaces and smooth muscle bundles may be seen.
 - Capsule is generally thin and clearly demarcated from neoplasm on one side and uninvolved thyroid tissue on the other side, which is usually compressed and may be atrophic.
- Capsule may vary in thickness from thin and regular to thick and irregular but tends to retain relative uniformity in thickness, enveloping the lesion without wide variations in thickness.
- Typically envelops lesion, remaining peripheral to and not within lesion
- Markedly thickened capsule should engender ample sampling to include tumor-to-capsule-to-parenchymal interface to exclude possible presence of an invasion that may confer a diagnosis of carcinoma.
- Composed of relatively uniform-appearing colloid-filled follicles with varying growth patterns that may include:
 - Normofollicular (simple)
 - Macrofollicular (colloid)
 - Microfollicular (fetal)

Fig. 28-6. Staining for colloid.

(Left) This cellular tumor was encapsulated without evidence of invasive growth or features of papillary thyroid carcinoma. Colloid is present but may not be readily appreciated on hematoxylin and eosin stains. (Right) Periodic acid Schiff (PAS) staining assists in highlighting the presence of colloid.

- Solid (embryonal)
- Trabecular (embryonal)
- Organoid (cell nests) and/or insular:
 - Presence of insular growth pattern does not convey a diagnosis of poorly differentiated (“insular”) thyroid carcinoma:
 - Requisite criteria for poorly differentiated thyroid carcinoma includes presence of increased mitotic activity and necrosis with or without invasion; see later in chapter for discussion on poorly differentiated thyroid carcinoma
- In general, follicular adenomas usually show single architectural pattern but may show an admixture of patterns:
 - Although not pathognomonic, a neoplasm with a variety of growth patterns should raise suspicion for papillary thyroid carcinoma.
- Cellularity and cytologic appearance of follicular adenoma varies from tumor to tumor and even within the same tumor:
 - Neoplastic cells are generally uniform with defined cell borders.
 - Nuclei tend to:
 - Be round to oval with coarse to hyperchromatic nuclear chromatin, smooth (rounded) nuclear contours, absent to inconspicuous nucleoli, and a variable amount of amphophilic to eosinophilic cytoplasm:
 - Granular eosinophilic cytoplasm may be present not as brightly eosinophilic as present in oncocytic (Hürthle) cells
- In association with granular eosinophilic cytoplasm nuclei may be enlarged with vesicular-appearing nuclei and some irregularities in size and shape, but nuclear chromatin tends to remain coarse and overall findings do not reach level of papillary thyroid carcinoma.
 - Align along basal aspect of cell.
 - Eosinophilic nuclear (pseudo)inclusions may rarely be present.
- Colloid-filled follicles are generally readily apparent but in some instances may be difficult to identify.
 - Periodic acid Schiff (PAS) stains assist in identifying presence of colloid.
- Follicular adenomas are well vascularized, and stromal component includes small to large vascular spaces:
 - Neoplastic cells can be seen within stromal vascular spaces but any neoplastic foci in vascular spaces within the tumor itself do not qualify as a carcinoma.
- Rare mitotic figures can be seen:
 - Presence of increased mitotic activity (>3-5 mitoses per 10 high power fields) and necrosis should be of concern and raise suspicion for a carcinoma.
- Degenerative stromal changes may uncommonly be seen and not as frequently found as in adenomatoid nodules:
 - Papillary or pseudopapillary architecture may be present but cytomorphologic (i.e., nuclear) findings associated with papillary thyroid carcinoma are not present.
 - Term papillary adenoma has been used for such lesions but the use of this designation should be avoided.
- Immunohistochemistry:
 - Thyroglobulin, thyroid transcription factor-1 (TTF-1, nuclear), and PAX8 (nuclear) positive
 - Cytokeratins (AE1/AE3, CK7, CK8, CK18) positive
 - CK19 negative
 - CD56 positive (membranous)
 - Calcitonin, synaptophysin, chromogranin negative
- Cytogenetics and molecular genetics:
 - RAS mutation in 20% to 40%:
 - Lower incidence in follicular adenoma, oncocytic type
 - PAX-PPAR γ translocation in 5% to 20%
 - Absence of:
 - RET/PTC translocation
 - BRAF mutation
 - PTEN mutation
 - PIK3CA/AKT pathway mutation

TABLE 28-7 Follicular Adenoma versus Adenomatoid Nodule

Feature	Follicular Adenoma	Adenomatoid Nodules
Number	Solitary	Multiple
Capsule	Well-developed, completely surrounding mass; appears rather uniform in thickness and appearance	Poor encapsulation; a capsule may be present but it does not completely encapsulate mass; in association with retrogressive changes fibrosis may envelop lesion but appears irregular of variable thickness, including marked thickening within and around lesion(s)
Adjacent thyroid gland	Compression of surrounding gland	No compression of surrounding gland
Growth as compared to the rest of the thyroid gland	Different growth pattern in adjacent gland	Comparable growth pattern in adjacent gland
Appearance as compared to the rest of the thyroid gland	Uniform cellularity dissimilar to remainder of gland	Variable cellularity similar to those outside nodules
Degenerative changes	May be present but not common	Frequently present
Clonality	Monoclonal cell population	Polyclonal cell population; studies have shown that at least some adenomatoid nodules are monoclonal with cytogenetic abnormalities, aneuploidy, and oncogenic mutations to support a neoplastic origin

Differential Diagnosis

- Adenomatoid nodule (Table 28-7)
- Follicular carcinoma:
 - Differentiating features separating follicular adenoma from follicular carcinoma is presence of invasion, including capsular invasion and/or vascular invasion:
 - See [Follicular Carcinoma](#) later in chapter for detailed discussion of vascular and capsular invasion.
 - Features in an adenoma raising concern for a possible diagnosis of carcinoma include:
 - Thickened fibrous capsule
 - Increased mitotic activity and/or necrosis
 - Diffuse nuclear atypia
 - No known molecular test at present assisting in differentiating follicular adenoma from follicular carcinoma
- Papillary thyroid carcinoma
- Medullary thyroid carcinoma

Treatment and Prognosis

- Conservative surgery (lobectomy) is preferred treatment.
- No recurrences or metastases

HISTOLOGIC TYPES OF FOLLICULAR ADENOMAS (Box 28-2)

- Generally, histologic variants of follicular adenoma do not confer on a given neoplasm any difference in

BOX 28-2 Histologic Types of Follicular Adenomas

- Follicular adenoma, oncocytic (Hürthle cell)
- Hyalinizing trabecular adenoma (paraganglioma-like)
- Follicular adenoma with atypical features
- Follicular adenoma, clear cell
- Follicular adenoma, signet ring cell
- Follicular adenoma with intracellular fat droplets
- Mucinous follicular adenoma (follicular adenoma with mucinous stroma)
- Follicular adenoma with spindle cell metaplasia
- Follicular adenoma with papillary architecture
- Follicular adenoma with bizarre nuclei
- Follicular adenoma with mesenchymal cell components
- Hyperfunctioning adenoma (toxic or “hot” adenoma)

clinical parameters or biologic behavior as compared to conventional types of follicular adenomas.

Follicular Adenoma, Oncocytic Type (Figs. 28-7 through 28-9)

Definition: Follicular epithelial cell-derived neoplasm dominated by presence of mitochondria-rich cells (i.e., oncocytes, oxyphilic cells) without evidence of invasion or metastasis.

- Terminology derived from the Greek word meaning “swollen”
- Results from increase in mitochondrial content of a cell
 - By light microscopy, an oncocytic cell is one that has a prominent granular eosinophilic-appearing cytoplasm.

Fig. 28-7. Fine-needle aspiration biopsy (FNAB), follicular adenoma, oncocytic type.

A, The cells are large with abundant granular cytoplasm appearing gray-blue (Diff-Quik). Note the low nuclear-cytoplasmic ratio. Very cellular oncocytic follicular neoplasms have little or no colloid; the cells tend to form small loosely cohesive groups or shed singly.

B, Papanicolaou stained smear shows oncocytic features manifested as cytoplasmic granularity. The cytoplasm is usually more abundant than in nononcocytic follicular cells. The nuclei are round, with readily apparent nucleoli. The FNAB diagnosis was “follicular neoplasm or suspicious for a follicular neoplasm, oncocytic (Hürthle) cell type (Bethesda IV).” A lobectomy was performed and the lesion proved to be a follicular adenoma.

- Should be distinguished from cells with cytoplasmic eosinophilia, which:
 - Has eosinophilic appearance of cytoplasm in hematoxylin and eosin stain (H&E)-stained sections but lacks granularity and bright pink appearance of oncocytic cells
- Oncocytic change in thyroid gland not restricted to follicular cells as it can also occur in:
 - Neoplastic C-cells (i.e., oncocytic medullary thyroid carcinoma [MTC])

Synonyms: Hürthle cell adenoma; oncocytic adenoma; oxyphilic cell adenoma; Askanazy cell adenoma

Fig. 28-8. Follicular adenoma, oncocytic type.

The tumor is completely encapsulated and characterized by an orange color.

BOX 28-3 Thyroid Lesions with Oncocytic Cells

Non-Neoplastic Lesions

- Nodular goiter (adenomatoid nodules)
- Chronic lymphocytic (Hashimoto) thyroiditis
- Graves disease
- Postradiation
- Aging

Neoplasms

- Follicular adenoma variants
- Follicular carcinoma variants
- Papillary carcinoma variants
- Medullary carcinoma
- Undifferentiated (anaplastic) thyroid carcinoma

- Hürthle originally described the cell that is now felt to represent parafollicular cell or C-cell of ultimobranchial derivation and not the oncocyte; description of oncocyte attributed to Askanazy
- Use of designation oncocytic (Hürthle, oxyphilic) is purely descriptive, indicative of a type of change in a cell and NOT indicative of any specified biologic behavior in a thyroid tumor
- Too often, assumption made that diagnosis of “Hürthle cell neoplasm” qualifies tumor as malignant, essentially being synonymous with a follicular carcinoma:
 - Erroneous assumption as oncocytic cell changes can be seen in non-neoplastic and neoplastic (benign and malignant) thyroid lesions (Box 28-3).

Clinical

- Similar demographics, clinical presentation, treatment, and biology to “conventional” follicular adenoma

Fig. 28-9. Follicular adenoma, oncocytic type.

A, Thinly encapsulated tumor. **B** and **C**, Lesional cells are characterized by the presence of abundant eosinophilic granular-appearing cytoplasm. Nuclear enlargement is present but in spite of the nuclear enlargement the nuclei remain round to oval with dispersed nuclear chromatin and enlarged eosinophilic nucleoli. A variable amount of colloid is present. **D**, Colloid may calcify and simulate the appearance of psammoma bodies (*arrowheads*).

- Serum thyroglobulin measurement reliable biomarker for thyroid cancer recurrence but shown to have poor accuracy for predicting malignancy in follicular neoplasms with oncocytic cells

Pathologic Features

Fine-Needle Aspiration Biopsy

- FNAB diagnosis is “follicular neoplasm or suspicious for a follicular neoplasm, oncocytic (Hürthle) cell type (Bethesda IV),” which informs treating physician that a neoplasm is present requiring surgical removal (e.g., lobectomy)
- Smears or aspirates dominated by enlarged oval to polygonal cells, often in sheets, that have abundant, granular-appearing cytoplasm:
- Nuclei tend to be enlarged, round to oval, eccentrically located with prominent eosinophilic nucleoli.

- Binucleated cells can be seen.
- Nuclear chromatin tends to be coarse.
- Colloid is minimal to absent.

Gross

- Similar to “conventional” follicular adenoma except that oncocytic cell change imparts distinct bright orange to brown coloration
- Vary in size and may be quite large (>4 cm):
 - Large size may correlate to presence of malignant neoplasm (follicular carcinoma, oncocytic type) but does not uniformly correlate to malignancy.

Histology

- Similar histologic features as “conventional” follicular adenoma:
 - Encapsulated tumors

- Capsule may vary in thickness.
 - No capsular and/or vascular invasion
- Growth patterns may include:
 - Follicular
 - Microfollicular
 - Solid
 - Trabecular
 - Organoid
 - Papillary architecture
 - May be focal or extensive
 - Prominent/extensive papillary growth may be seen as a retrogressive phenomenon occurring spontaneously or following fine-needle aspiration biopsy
 - Nuclear characteristics diagnostic for papillary carcinoma absent
- Characterized by presence of cells with abundant eosinophilic granular-appearing cytoplasm
 - Cytoplasmic margins often distinctly seen
- Presence of oncocyctic cytoplasm often causes nuclear enlargement but in spite of nuclear enlargement nuclei tend to remain rather uniform-appearing round to oval with coarse to granular to vesicular-appearing chromatin and presence of distinct (centrally located) eosinophilic nucleoli
 - Nuclear grooves and nuclear (pseudo)inclusion may be identified.
 - Presence of such features not diagnostic for papillary thyroid carcinoma and can be seen in benign thyroid lesions/neoplasms
- Clear cell change may be seen:
 - May be juxtaposed or intermixed with oncocyctic cells
 - Caused by swelling of mitochondria
- Colloid:
 - May be readily apparent or limited in extent
 - May calcify including concentric laminations, suggesting presence of psammoma bodies and a possible diagnosis of papillary thyroid carcinoma:
 - Typically located within lumens, not usual location in papillary thyroid carcinomas
 - Cytomorphologic (i.e., nuclear) features not those of papillary thyroid carcinoma
- Oncocyctic cells owing to oxygen-sensitive nature of mitochondria more readily undergo retrogressive changes either spontaneously or following traumatic event such as post-fine-needle aspiration biopsy; such alterations may include:
 - Infarction
 - Necrosis
 - Hemorrhage (recent and remote in form of hemosiderin-laden macrophages)
 - Papillary architecture
 - Cyst formation
 - Fibrosis
 - Calcifications
- Term Hürthle cell neoplasm of uncertain malignant potential has been ascribed to those tumors showing worrisome but inconclusive features of malignancy, including:
 - Smaller cells with high nuclear-to-cytoplasmic ratio
 - Increased mitotic activity
 - Because these tumors have uniformly followed a benign clinical course this terminology is not advocated and designation of follicular adenoma, oncocyctic type is preferred.
- Histochemistry:
 - Stains for mitochondria may be positive and include:
 - Phosphotungstic acid hematoxylin (PTAH): red staining
 - Novelli stain: dark purple staining
- Immunohistochemistry:
 - Cytokeratins, thyroglobulin, and TTF-1 positive:
 - Thyroglobulin reactivity less intense than in nononcocyctic follicular cells
 - Chromogranin, synaptophysin, and calcitonin negative
 - Low proliferation indices (less than 5%) by KI67 (MIB-1) staining
- Electron microscopy:
 - Oncocyctic cells are packed with mitochondria.
 - Mitochondrial abnormalities can be seen, including quantitative and qualitative (size, shape, content) changes.
- Cytogenetics and molecular genetics:
 - RET/PTC rearrangements may be present:
 - Questionable relevance relative to diagnosis and classification
 - May reflect very low rearrangement level using highly sensitive detection method or tumor heterogeneity
 - Additional findings reported include:
 - Large deletions of mitochondrial DNA (mtDNA), mutations of mtDNA genes coding for oxidative phosphorylation (OXPHOS) proteins, and mutations of nuclear genes coding also for mitochondrial OXPHOS proteins
 - Such mitochondrial alterations lead to energy production defects in Hürthle cell tumors:
 - Increased proliferation of mitochondria may reflect compensatory mechanism for such defects and is associated with overexpression of factors involved in mitochondrial biogenesis
 - Mitochondrial abnormalities also thought to play a major role in predisposition for necrosis instead of apoptosis, which seems to be blocked in most Hürthle cell tumors

Differential Diagnosis

- Follicular carcinoma, oncocytic type:
 - Diagnosis of follicular carcinoma, oncocytic type made in presence of capsular or vascular invasion
 - In absence of invasive growth, features found in an encapsulated follicular neoplasm (including the oncocytic follicular adenoma) that may increase concern for malignancy include:
 - Increased cellularity in particular at the tumor-to-capsule-to-stromal interface
 - Smaller cells with increased nuclear-to-cytoplasmic ratio
 - Increased mitotic activity
 - Necrosis either individual cell or confluent foci
- Papillary thyroid carcinoma (PTC):
 - Usual type:
 - Does not have oncocytic cytoplasm but nuclear enlargement and to some degree nuclear clearing seen in follicular adenoma, oncocytic type may be mistaken for PTC
 - Tall cell type:
 - Some authorities consider tall cells to be variant of oncocytic.
- Medullary thyroid carcinoma, oncocytic type:
 - Oncocytic change in thyroid gland not restricted to follicular cells because it can also occur in neoplastic C-cells (i.e., oncocytic medullary thyroid carcinoma [MTC]):
 - Immunohistochemical staining for calcitonin, neuroendocrine markers present in MTC and absent in follicular epithelial cell tumors
 - Immunohistochemical staining for thyroglobulin and TTF1 present in oncocytic follicular adenoma and absent in MTC

Treatment and Prognosis

- Conservative surgery (lobectomy) is preferred treatment and considered curative.

Hyalinizing Trabecular Adenoma/Tumor

(Figs. 28-10 and 28-11)

Definition: Encapsulated follicular epithelial-derived tumor with trabecular growth pattern and presence of prominent intratrabecular hyalinization located in cytoplasm of lesional cells and in extracellular space.

Synonym: Paraganglioma-like adenoma of thyroid (PLAT)

Terminology

- Controversy among authorities whether hyalinizing trabecular adenoma should be considered variant of papillary thyroid carcinoma (PTC) based on:
 - Occurrence of hyalinizing trabecular adenoma in the setting of lymphocytic thyroiditis or in patients

with a history of radiation therapy, two settings more typically seen in association with papillary thyroid carcinoma

- Co-existence with typical thyroid papillary carcinoma
- Presence of HTA-like foci in typical thyroid papillary carcinoma
- Overlapping nuclear features shared with PTC
- Demonstration of *RET/PTC* translocation in percentage of cases
- Occasional presence of nodal metastasis showing pattern of growth similar to hyalinizing trabecular adenoma
- Weighing in favor for categorization as adenoma includes:
 - Overwhelming majority of solitary encapsulated thyroid lesions showing feature of hyalinizing trabecular adenoma behave as benign neoplasms
 - *BRAF* mutations a finding present in PTCs not reported in hyalinizing trabecular adenoma
 - Micro (mi)-RNAs known to be upregulated in PTC were downregulated in hyalinizing trabecular adenoma
- At present, most authorities view hyalinizing trabecular adenoma as a benign neoplasm but given similarities to papillary carcinoma designation hyalinizing trabecular tumor recommended

Clinical

- Affects women more than men; occurs over a wide age range from the third through eighth decades of life
- Clinical presentation is that of an asymptomatic neck mass.
- May occur in any portion of the thyroid gland
- Radiology:
 - Thyroid imaging (^{123}I or $^{99\text{m}}\text{technetium}$): “cold” nodule; may appear as a “hot” nodule
- Etiology unknown:
 - Several cases reported following radiation exposure

Pathologic Features

Fine-Needle Aspiration Biopsy

- Cohesive aggregates radially oriented around hyaline material
- Cells with abundant cytoplasm and low nuclear-to-cytoplasmic ratio
- Intranuclear cytoplasmic inclusions, nuclear grooves, and nuclear overlapping are common (best seen with the Papanicolaou method):
 - Cytoplasmic yellow bodies useful cytomorphologic indicator of hyalinizing trabecular adenoma; see details under microscopic description below

Fig. 28-10. Hyalinizing trabecular adenoma/tumor.

Tumor characterized by **(A)** trabecular and organoid (cell nest; paraganglioma-like) growth pattern with fibrovascular stroma (paraganglioma-like) and prominent hyalinization; numerous variably sized cystic spaces are characteristically present; **(B)** elongated cells that may be oriented perpendicular to the fibrovascular stroma; **(C)** oval to elongated nuclei with irregularities in size and shape, nuclear grooves, and finely dispersed nuclear chromatin; **(D)** eosinophilic nuclear (pseudo) inclusions that may be numerous in any given case; **(E)** perinucleolar halos (*arrows*); and **(F)** yellow bodies (*arrowheads*) often located close or adjacent to and indenting nuclei (paranuclear) appearing surrounded by clear halo.

Fig. 28-11. Hyalinizing trabecular adenoma/tumor, immunohistochemical staining.

Immunohistochemical staining in hyalinizing trabecular adenoma/tumor includes **(A)** thyroglobulin with staining of lesionsal cells as well as follicles and cysts but **(B)** may be limited to follicles and microcysts with minimal to absent staining of the lesionsal cells; **(C)** TTF-1 (nuclear staining) and **(D)** MIB-1 (Ki67) (membranous).

- May be present but uncommon in papillary thyroid carcinoma and in follicular adenomas (including oncocytic variant)
- Diff-Quik–stained smears highlighted the hyaline material (metachromatic), perinucleolar clearing, and cytoplasmic bodies.
- Overall features may suggest papillary thyroid carcinoma or even medullary thyroid carcinoma but combination of a bloody background, radially oriented cohesive cells, cells with abundant cytoplasm, nuclei with very frequent cytoplasmic inclusions and grooves, and presence of hyalin should suggest hyalinizing trabecular adenoma.

Gross

- Well-circumscribed, single, solid, encapsulated or circumscribed tumor measuring from 1 to 5 cm in diameter but usually less than 2.5 cm
- Cut surface shows tendency to appear lobulated.

Histology

- Circumscribed to encapsulated tumor characterized by trabecular to organoid growth with fibrovascular stroma:
 - Trabeculae may appear coiled.
 - Lobulated growth can be seen.
- Presence of prominent extracellular and intracellular hyalinization
- Follicle formation is minimal or absent:
 - Tumor has little colloid formation.
- Characteristically, microcysts and larger cystic spaces are seen:
 - Possibly represent abortive follicle formation
- Cells are elongated and sharply outlined oriented perpendicular to fibrovascular stroma.
- Nuclei are round, oval, or elongated with
 - Nuclear grooves
 - Eosinophilic nuclear (pseudo)inclusions

- Perinucleolar halos:
 - Represent giant lysosomes as seen by electron microscopy
- Cytoplasm is finely granular with acidophilic, amphophilic, or clear appearance.
- Cytoplasmic yellow bodies common and frequent finding representing very useful finding in FNAB or in surgical pathology material in diagnosis:
 - On H&E staining, appear as solid, round, pale yellow cytoplasmic inclusions surrounded by clear halo
 - Are refractile with a microvacuolated or granular substructure
 - Located close to the nucleus (paranuclear) sometimes indenting the nucleus resulting in semilunar deformity of nucleus (nuclear molding); rarely, may be intranuclear
 - Positive staining with PAS, GMS, alcian blue-PAS, Sudan black B
 - Ultrastructurally, cytoplasmic intermediate filaments, myelinosomes with parallel whorled and stacked membranes (“fingerprint” bodies), swollen mitochondria and huge membrane-limited organelles composed of disrupted membranes and microtubules, vesicles, and myelinosomes with “fingerprint” bodies; the organelles may occupy a semilunar depression in the nucleus.
 - Yellow bodies are consistent with giant lysosomes.
 - Yellow bodies are uncommon but may be identified in other thyroid neoplasms, including papillary carcinoma, follicular carcinoma, follicular adenoma or carcinoma with oncocytic cells
- Calcifications including calcified colloid and/or psammoma body-like formations can be seen.
- Chronic lymphocytic thyroiditis is often found in surrounding thyroid gland.
- Occasional mitotic figure may be identified
- Histochemistry:
 - Hyalinized foci may suggest presence of amyloid but staining for amyloid including Congo red is negative.
- Immunohistochemistry:
 - Thyroglobulin and TTF-1:
 - Thyroglobulin may be limited to follicles and microcysts.
 - TTF-1 (nuclear staining) present in lesional cells
 - Unique cell membrane and cytoplasmic granular immunoreactivity for MIB-1 (Ki67):
 - Present with some monoclonal antibodies but not polyclonal antibodies suggesting this staining is artifactual
 - Calcitonin, chromogranin, synaptophysin negative
 - Galectin-3 expression may be present:

- Variable expression; seen in some but not all cases and when present is never as intense as might be present in papillary thyroid carcinoma

- Until recently HBME-1 negative but immunoreactivity reported with staining of lesional cells and intratrabecular hyaline matrix material identified
- CD56 reactivity (membranous) may be present.
- Discrepant results reported for high-molecular-weight cytokeratins and CK19
- Cytogenetics and molecular genetics:
 - Presence of *RET/PTC* somatic translocations with similar (or greater) frequency to that of thyroid papillary carcinoma.
 - Absence of *BRAF* mutation
 - Micro (mi)-RNAs known to be upregulated in PTC not found in hyalinizing trabecular adenoma

Differential Diagnosis

- Other thyroid lesions/neoplasms with trabecular growth and hyalinization:
 - Adenomatoid nodules
 - Lymphocytic thyroiditis
- Papillary thyroid carcinoma
- Medullary thyroid carcinoma
- Paraganglioma

Treatment and Prognosis

- Conservative surgery (lobectomy or subtotal thyroidectomy)
- Excellent prognosis following surgical removal

Additional Notes

- Hyalinizing trabecular neoplasms with minimally invasive growth have been identified and termed.

Hyalinizing Trabecular Carcinoma

- Considered to be malignant counterparts of hyalinizing trabecular adenoma:
- Extremely rare:
 - Some cases reported may in fact represent cribriform-morular variant of papillary thyroid carcinoma that may be associated with familial-adenomatous polyposis (FAP)
 - Measure from 2.5 to 4 cm
 - Histology is identical to that hyalinizing trabecular adenoma except there is capsular and/or vascular invasion.
 - These minimally invasive tumors are biologically low grade.
- Conservative surgical removal is indicated with close follow-up.

Fig. 28-12. Atypical follicular adenoma.

Follicular adenoma with atypical features may include tumors with (A) necrosis and nuclear atypia; (B) increased mitotic activity (arrow). In such tumors definitive features for carcinoma including invasive growth and/or nuclear features diagnostic for papillary thyroid carcinoma are absent.

Follicular Adenoma with Atypical Features (Fig. 28-12)

Definition: Any encapsulated follicular neoplasm that lacks features for papillary thyroid carcinoma but shows histologic features suspicious for a more aggressive neoplasm (i.e., carcinoma) without definitive evidence of either capsular or vascular space invasion.

Synonyms: Atypical follicular adenoma; follicular tumor/neoplasm of uncertain malignant potential; well-differentiated (follicular) tumor of uncertain malignant potential

Clinical

- Demographics and clinical presentation similar to those of (typical) follicular adenoma

Pathology

- Macroscopic and FNAB features similar to those of (typical) follicular adenoma
- Histologic features that raise possibility of a potentially more aggressive follicular neoplasm (i.e., carcinoma) and that may be considered as “atypical” include:
 - Increased mitotic activity in absence of necrosis:
 - Benign endocrine organ neoplasms generally are amitotic, and presence of mitoses raises concern for possibility of a malignant tumor.
 - However, as an isolated finding increased mitotic activity is not indicative of malignancy.
 - In presence of necrosis consideration for a possible diagnosis of poorly differentiated thyroid carcinoma should be entertained (see under Malignant Neoplasms)
 - Necrosis (in absence of previous FNAB):
 - Presence of coagulative type necrosis considered potentially worrisome features for carcinoma (even more so than mitotic activity)
 - Pronounced cellular proliferation with diffuse nuclear atypia
 - Categorization of a tumor as being atypical or of uncertain biologic behavior may include encapsulated follicular tumors in which tumor extends only to inner half of its capsule but falling short for definitive evidence of capsular invasion, which would allow diagnosis of follicular carcinoma
- Classification of an encapsulated follicular tumor showing equivocal cytomorphologic features for papillary thyroid carcinoma or limited foci diagnostic for papillary thyroid carcinoma remains controversial:
 - If extent of change is significant/widespread (to date there is no clear definition of what constitutes “significant” or “widespread”) then diagnosis of encapsulated (noninvasive) papillary thyroid carcinoma, follicular variant, can be made although recent recommendation is to replace the term “follicular variant of PTC” with “noninvasive follicular tumor with papillary-like features.” (See under PTC in malignant neoplasms.)
 - If nuclear features are equivocal and there is no invasion, then such a tumor can be termed as an atypical adenoma.
 - If features are equivocal but there is definitive evidence of invasion, then tumor can be diagnosed as carcinoma:
 - In such circumstances specific designation of type of carcinoma (i.e., papillary versus follicular) is academic because treatment should be similar.
 - Depending on one’s level of confidence following designations can be used for a neoplasm

with invasive growth but equivocal cytomorphologic features:

- Carcinoma, favor papillary thyroid carcinoma, follicular variant
- Carcinoma, favor follicular carcinoma, minimally invasive
- Well-differentiated carcinoma, not otherwise specified
- In follicular neoplasm considered to be atypical (or in any encapsulated thyroid neoplasm with questionable features for malignancy) most critical issue is adequate and appropriate sectioning to evaluate tumor-capsule-thyroid parenchymal interface for evidence of invasive growth:
 - Guideline to number of sections considered adequate to exclude the presence of invasion include:
 - For a tumor measuring <6 cm = submit entire tumor
 - For a tumor measuring 6 cm = submit at least 10 blocks
 - For a tumor measuring >6 cm = submit one additional block per centimeter of tumor
- Cytogenetics and molecular genetics:
 - Telomerase reverse transcriptase (TERT) promoter mutations (C228T and C250T) found in many malignancies, including in thyroid carcinomas, may be present in atypical follicular adenoma (and less commonly in “usual” follicular adenoma).
 - May occur as early genetic event in thyroid follicular tumors that have not developed malignant features on routine histopathologic workup

Differential Diagnosis

- Follicular carcinoma, minimally invasive
- Adenomatoid nodules
- Papillary thyroid carcinoma, follicular variant

Treatment and Prognosis

- Treatment is surgical removal (similar to usual types of follicular adenomas):
 - Surgery is conservative in extent limited to the affected portion(s) of the thyroid gland (lobectomy or subtotal thyroidectomy).
 - Prognosis is excellent.
 - Long-term follow-up shows atypical follicular adenomas to behave in a benign course.

FOLLICULAR ADENOMAS CLASSIFIED BY CELL TYPE OR GROWTH PATTERN

- All have similar demographics, clinical presentation, treatment, and biology as “conventional” follicular adenomas.

Follicular Adenoma with Clear Cells

(Figs. 28-13 and 28-14)

- Predominantly or exclusively composed of cells with clear (empty) to finely granular-appearing cytoplasm:
 - Clear-appearing cytoplasm may be due to:
 - Massively dilated mitochondria appearing as intracytoplasmic vesicles on electron microscopy
 - Intracytoplasmic glycogen, lipid, or mucin accumulation
 - Intracytoplasmic thyroglobulin deposition:
 - Intracellular thyroglobulin accumulation may be related to effects of thyroid stimulating hormone (TSH) causing increased thyroglobulin deposition within cell cytoplasm due to inability of cell to release or excrete it.
 - Clear cell change may be closely linked to oncocytic cell change representing “end-stage” cytoplasmic changes of a tumor that once was predominantly oncocytic.
- Nuclei are centrally situated, are small, round, and regular with hyperchromasia with or without sharp cell outlines.
- Growth pattern is usually follicular but may include trabecular or solid growth.
- Colloid-containing follicles may be absent or only focally identified; periodic acid Schiff (PAS) is helpful in identifying the presence of colloid.
- Histochemistry:
 - Diastase-sensitive, PAS-positive intracytoplasmic material
- Immunohistochemistry:
 - Thyroglobulin, TTF-1 (nuclear), and PAX8 (nuclear) positive but may be focal and of limited intensity
 - Calcitonin and neuroendocrine cell markers (chromogranin and synaptophysin) negative
 - CD10, renal cell carcinoma (RCC) antibody, carbonic anhydrase IX (CAIX), PAX2, PAX8 negative

Differential Diagnosis

- Metastatic renal cell carcinoma (Table 28-8)
- Follicular carcinoma with clear cells
- Papillary thyroid carcinoma
- Parathyroid lesions
- Medullary thyroid carcinoma with clear cells

Follicular Adenoma with Signet Ring Cells (Fig. 28-15)

Synonym: Signet ring cell adenoma

Fig. 28-13. Follicular adenoma with clear cells.

A, Left, Solitary encapsulated thyroid tumor with a nested growth and readily apparent colloid-filled follicles; **right,** colloid-filled follicles with small round to oval hyperchromatic nuclei and characteristic clear cytoplasm. **B and C,** In this example there is no evident colloid formation, potentially raising concern for a possible diagnosis of metastatic renal cell carcinoma. Immunohistochemical staining (see next image) confirms the diagnosis of a follicular adenoma with clear cells. **D,** Juxtaposition of cells with clear cytoplasm (*right side*) and cells with oncocytic cytoplasm (*left side*). Clear cell change may be closely linked to oncocytic cell change representing “end-stage” cytoplasmic changes of a tumor that once was predominantly oncocytic.

Pathology

Fine-Needle Aspiration

- Signet ring cells are round to oval, with large cytoplasmic vacuoles and hyperchromatic, eccentric nuclei.
- Colloid in the background may be scanty.

Histology

- Characterized by cells that have large intracytoplasmic vacuoles that result in eccentric displacement of cell nucleus creating a signet ring appearance:
 - Cytoplasm appears clear to acidophilic to finely granular.
- Nuclei are hyperchromatic and flattened or semi-lunar in appearance but may retain a rounder appearance.
- Growth pattern is microfollicular and nested; colloid is readily apparent.
- Histochemistry:
 - Diastase-resistant, PAS-positive intracytoplasmic material
 - Mucicarmine and alcian blue may be positive.
 - Thyroglobulin is a sialic acid-containing glycoprotein, and therefore thyroglobulin will stain with periodic acid Schiff (PAS) and acid mucin stains (e.g., alcian blue at pH 2.5, sulfomucin).

Fig. 28-14. Immunohistochemical staining in follicular adenoma with clear cells.

Immunohistochemical staining in a follicular adenoma with clear cell change includes **(A)** thyroglobulin (strong staining of colloid and granular cytoplasmic staining); **(B)** TTF-1 (nuclear). Such findings differentiate a follicular adenoma with clear cells from metastatic renal cell carcinoma.

Fig. 28-15. Follicular adenoma with signet ring cells.

A, Characteristically the cells have large intracytoplasmic vacuoles resulting in eccentric displacement of nucleus and creating a signet ring appearance; cytoplasm appears acidophilic to eosinophilic. **B**, Thyroglobulin reactivity is present.

TABLE 28-8 Follicular Tumors with Clear Cells versus Metastatic Renal Cell Carcinoma

Features	Follicular Adenoma/Carcinoma with Clear Cells	Metastatic Renal Cell Carcinoma
Luminal secretion	Colloid; will be PAS positive	No colloid; red blood cells; pseudofollicles
Nested growth with fibrovascular stroma	Present	Present
Cytoplasm	Foamy appearing	Clear with distinct cell borders
Nuclear	Round; dispersed or coarse chromatin	Small, round, hyperchromatic
Glycogen (diastase-sensitive, PAS-positive)	Yes, but colloid will be diastase resistant	Yes; intensely positive
IHC findings	Thyroglobulin, TTF-1, PAX8 positive; CD10, RCC, CAIX, PAX2 negative	Thyroglobulin, TTF-1 negative CD10, RCC, CAIX, PAX2, PAX8 positive

CAIX, Carbonic anhydrase IX; IHC, immunohistochemistry; RCC, renal cell carcinoma antibody; TTF-1, thyroid transcription factor 1.

- Mucicarmine, a stain for neutral mucins, is positive but usually weakly positive:
 - Mucicarminophilia seen in the signet ring cells is attributed to intracytoplasmic thyroglobulin accumulation.
- Immunohistochemistry:
 - Strong thyroglobulin reactivity is present:
 - Intense thyroglobulin immunoreactivity correlates to intracytoplasmic thyroglobulin deposition that, in turn, gives cell its signet ring appearance.
 - Intracellular thyroglobulin accumulation may be related to effects of thyroid-stimulating hormone (TSH), causing increased thyroglobulin deposition within cell cytoplasm due to inability of cell to release or excrete it.
 - Weak thyroglobulin staining may be present in a given example.
 - TTF-1 and PAX8 (nuclear) immunoreactive
 - Calcitonin and neuroendocrine cell markers (chromogranin and synaptophysin) are negative.

Differential Diagnosis

- Metastatic adenocarcinoma (lung, gastrointestinal tract)

Follicular Adenoma with Intracellular Fat Droplets (Fig. 28-16)

Synonym: Lipid-rich adenoma

- Follicular adenoma with fat is extremely rare.
- Fat in follicular epithelial cells may occur as a result of aging.

Fig. 28-16. Lipid-rich cell adenoma.

Oil red O stain for fat is positive. This tumor was characterized by cells with small to medium-sized intracytoplasmic vesicles that resulted in indentation of the centrally situated nucleus.

- Characterized by cells that have small to medium-sized intracytoplasmic vesicles that result in indentation of centrally situated nucleus.
- Histochemistry:
 - Oil red O or other fat stains will be positive.
- Immunohistochemistry:
 - Thyroglobulin and TTF-1 positive

Differential Diagnosis

- Thyrolipoma

Mucinous Follicular Adenoma or Follicular Adenoma with Mucinous Stroma (Fig. 28-17)

- Characterized by presence of abundant extracellular basophilic-appearing mucin
- Growth patterns include microcystic, reticular, or multicystic

Fig. 28-17. Follicular adenoma with mucinous stroma.

A, B, Encapsulated tumor showing variable cellularity characterized by presence of abundant extracellular basophilic-appearing mucin. The growth patterns include microcystic and reticular. The cells were thyroglobulin positive (not shown).

- Mucinous pools may be present.
- Signet ring cells may be identified.
- Extracellular mucin stains with alcian blue and colloidal iron but not with mucicarmine and DPAS
- Tumor cells positive for thyroglobulin and negative for calcitonin, CEA, galectin-3, HBME-1, and CK19
- Considered a degenerative phenomenon

Additional Alterations in Follicular Adenomas

- Follicular adenoma with spindle cell metaplasia (Fig. 28-18)
 - Variably seen in a given tumor:
 - May be focal or more diffuse
 - Short fascicles, storiform, or whorling growth
 - Bland cytomorphology lacking significant pleomorphism, mitotic activity, necrosis, or invasive growth
 - No cytomorphologic features diagnostic of papillary thyroid carcinoma
 - Immunoreactivity for:
 - Thyroglobulin, TTF-1, PAX8, and cytokeratin
 - Low proliferation indices (MIB1 or Ki67)
 - Spindle cell metaplasia can also be seen in adenomatoid nodules, follicular carcinoma, papillary thyroid carcinoma, and medullary thyroid carcinoma.
- Follicular adenoma with papillary architecture (Fig. 28-19)
 - Referred to as follicular adenoma with papillary hyperplasia or papillary adenoma
 - These lesions:
 - Have a tendency to occur in children and adolescents
 - Have papillae that often are wider as compared to the more narrower-appearing papillae seen in papillary thyroid carcinoma
 - Despite papillary architecture lack cytomorphology of papillary thyroid carcinoma
 - Have a benign biologic course
- Follicular adenoma bizarre nuclei (Fig. 28-20)
 - Presence of scattered bizarre hyperchromatic and pleomorphic nuclei in an otherwise usual follicular adenoma
 - Nuclear changes referred to as endocrine atypia
 - Cells are immunoreactive for thyroglobulin, TTF-1 (nuclear), and PAX8 (nuclear)
 - Negligible to low proliferation rate by Ki67 staining
- Follicular adenoma with mesenchymal cell components (Fig. 28-21)
 - Associated mesenchymal components may include:
 - Lipomatous stroma (thyrolipoma, adenolipoma)
 - Cartilage (chondroid metaplasia)
 - Bone (chondroid and osseous metaplasia)
 - Smooth muscle
 - Fibrous tissue
- Post-FNAB-infarcted follicular adenoma:
 - Infarction may be partial or complete.
 - Infarction may compromise histology, making recognition of nature of lesion difficult.
 - Infarction appears as coagulative necrosis with associated hemorrhage and a variable amount of inflammatory cells
 - With time, granulation tissue and macrophages may be present.
 - Peripheral rim of residual, viable tumor may be present, which may show marked reactive nuclear atypia.
 - In infarcted foci, architectural pattern of lesion is retained despite cellular necrosis.
 - PAS staining for colloid may be helpful in recognizing lesion as a follicular epithelial neoplasm.
 - Antigenicity of tumor often is retained, including cytokeratin and thyroglobulin reactivity.
 - Tumors with cytoplasmic oxyphilia due to high content of oxygen-sensitive mitochondria are more easily traumatized, potentially resulting in infarction and additional retrogressive changes.
- Hyperfunctioning adenoma (toxic or “hot” adenoma)
 - Rare occurrence
 - Associated with symptoms of hyperthyroidism due to autonomous production of thyroxine
 - “Hot” appearance on radioactive iodine scanning
 - Histologically shows hyperplastic foci with papillary growth with follicles lined by tall cuboidal cells
 - Histology reminiscent of that seen in Graves disease

Fig. 28-18. Follicular adenoma with spindle cells.

A, This encapsulated tumor showed foci of follicular adenoma (*upper right*) adjacent to areas composed of spindle-shaped cells with storiform growth and no evidence of colloid and/or follicular epithelial cell differentiation. **B**, Intimate admixture of colloid-filled thyroid follicles and spindle cells lacking evidence of follicular cell derivation is seen. Immunohistochemical staining shows the spindle cells to be reactive for **(C)** cytokeratin (AE1/AE3), **(D)** thyroglobulin, **(E)** TTF-1 (nuclear), and **(F)** PAX8 (nuclear).

Fig. 28-19. Follicular adenoma with papillary architecture.

A, Encapsulated follicular neoplasm with foci of papillary architecture. **B**, The nuclei are small, round to oval with coarse nuclear chromatin and aligned along the basal aspect of the cells lacking nuclear features diagnostic for papillary thyroid carcinoma. The papillae tend to be wider than the narrower appearance of papillae typically seen in papillary thyroid carcinoma.

Fig. 28-20. Follicular adenoma with nuclear atypia (endocrine atypia).

A and **B**, Focal areas of follicular adenoma showing the presence of bizarre hyperchromatic and pleomorphic nuclei. Such nuclear changes are referred to as endocrine atypia. The fact that these changes are focal and not diffuse and lacking other features that may raise concern for malignancy (e.g., necrosis, mitotic activity, invasion) should allow for a diagnosis of a benign (reactive) proliferation. Typical and bizarre cells are immunoreactive for **(C)** thyroglobulin and **(D)** TTF-1 (nuclear).

Fig. 28-21. Follicular adenoma with mesenchymal components.

A, B, In this example mature adipose tissue is intimately admixed with the adenoma (thyrolipoma; adenolipoma). Other mesenchymal components that can be seen in follicular adenomas may include cartilage, bone, smooth muscle, and fibrous tissue (not shown).

Fig. 28-22. Fine-needle aspiration biopsy of a solitary, solid thyroid mass.

A, The aspirate is cellular with absent colloid. Small cell clusters with syncytial configuration are present, as are isolated cells. A microfollicular pattern is focally present. **B,** Cells are monomorphic, enlarged with uniform, round to oval nuclei with evenly distributed, finely granular (coarse) chromatin, small to inconspicuous nucleoli, and pale to clear cytoplasm with indistinct cell margins. Anisokaryosis and anisochromatosis can be seen. The FNAB diagnosis was “follicular neoplasm or suspicious for a follicular neoplasm (Bethesda IV). A lobectomy was performed and the lesion proved to be a follicular carcinoma.

MALIGNANT FOLLICULAR EPITHELIAL NEOPLASMS

FOLLICULAR CARCINOMA (FC) (Figs. 28-22 through 28-31)

Definition: Malignant follicular epithelial cell, not belonging to papillary carcinoma, characterized by

invasive growth (i.e., capsular and/or vascular invasion) and/or metastatic disease.

Clinical

- Represents approximately 10% to 20% of all malignant thyroid tumors

Fig. 28-23. Follicular carcinoma.

The gross appearance of this thyroid tumor is identical to that of follicular adenoma. Only following histologic evaluation with identification of invasion was a diagnosis of follicular carcinoma rendered.

- More common in women than in men; occurs over a wide age range but is most common in the fifth to sixth decades of life:
 - Approximately one decade older than patients with papillary thyroid carcinoma
 - Rare but does occur in children and adolescents
- Clinical presentation usually solitary, painless neck mass:
 - Pain may occur later in disease course.
 - Initial presentation may be as a pulmonary metastasis or pathologic fracture secondary to osseous metastasis.
- Patients are usually euthyroid:
 - Uncommonly, patients may present with clinical manifestations of hyperthyroidism.
- Radiology
 - On thyroid scan (^{123}I), most often solitary, “cold,” or hypofunctioning nodules
- Etiology:
 - Incidence greater in iodine-deficient regions of the world

Fig. 28-24. Follicular carcinoma with capsular invasion.

Various degrees of capsular invasion but in all images the tumor transgresses the entire thickness of the capsule with varying extension beyond the capsular delimitation, including mushroom-like protrusion.

Fig. 28-25. Follicular carcinoma with capsular invasion.

A through **C**, More extensive invasion including one or more nodules separate from the main mass, some within adjacent thyroid parenchyma. **C**, Clear-cut invasion beyond capsular delimitation is present with extensive invasion such that a capsule not readily identifiable supporting a diagnosis of a widely invasive follicular carcinoma. In addition, extensive vascular invasion was present in this case (not shown).

- Partly for this reason occurs in glands that have been enlarged for long periods
- Addition of supplemental iodine to diet associated with decrease in incidence of follicular carcinoma
- Development linked to:
 - Exposure to ionizing radiation:
 - Risk not as high as compared to that associated with papillary thyroid carcinoma
 - Pre-existing thyroid disease including:
 - Follicular adenoma:
 - Direct precursor lesion to follicular carcinoma
 - Goiter (adenomatoid nodules):
 - Predisposition owing to prolonged TSH stimulation, which in turn increases rate of cell proliferation that may result in increase chance of mutations in dividing cells
 - Familial syndromes such as phosphatase and tensin homolog (PTEN) hamartoma syndrome, which includes Cowden disease and other rare syndromes:
 - Cowden disease characterized by multiple mucocutaneous hamartomas and predisposition to malignant neoplasms, mostly breast and thyroid:
 - 10% to 20% develop follicular carcinoma

Pathology

Fine-Needle Aspiration Biopsy

- Excellent screening tool in evaluation of a thyroid mass but utility limited in presence of differentiated (nonanaplastic) follicular epithelial cell lesion differentiating follicular adenoma from follicular carcinoma
 - Differentiation primarily predicated on presence or absence of invasive growth (capsular or vascular) and not cytomorphology, a feature not seen in needle aspiration
 - Often FNAB diagnosis is “follicular neoplasm or suspicious for a follicular neoplasm (Bethesda IV),” which informs treating physician that a neoplasm is present that requires surgical removal (e.g., lobectomy)
- Cellular with minimal to absent colloid
- Cells often arranged in microfollicular pattern but trabecular pattern can also be seen.
 - Small three-dimensional clusters with syncytial configuration can be seen.
 - Isolated cells are often found.
- In general, cells are monomorphic and enlarged as compared to non-neoplastic follicular epithelial cells characterized by uniform, round to oval nuclei with evenly distributed, finely granular (coarse) chromatin, small to inconspicuous nucleoli, and pale to clear cytoplasm with indistinct cell margins.

Fig. 28-26. Equivocal capsular invasion.

Follicular neoplasms with equivocal capsular invasion including **(A and B)** less than complete transgression of the entire thickness of the capsule; **(C)** tangential sectioning; **(D)** presence of intracapsular blood vessels creating distortional changes and the suggestion of capsular invasion; note the rounded or smooth contour of the external edge of the lesion lying in the same plane as the thin fibrous capsule. In these examples there was no evidence of vascular invasion and, given the less-than-diagnostic features for invasion, should be diagnosed as an adenoma (arguable with atypical features) and not carcinoma.

- Nuclei may vary in appearance:
 - Anisokaryosis and anisochromatosis can be seen.

Histology

- Similar to their benign counterparts follicular carcinomas are encapsulated tumors:
 - Typically (but not always), capsule tends to be thicker than capsule in follicular adenoma:
 - May vary in thickness from 0.1 to 0.3 cm to thicker
 - For widely invasive follicular carcinomas a distinct, readily identifiable capsule may be absent.
- In general, usually shows single architectural pattern but may show admixture of growth patterns, including:
 - Follicular and/or microfollicular:
 - Uniform-appearing colloid-filled follicles
 - Solid
 - Trabecular
 - Insular:
 - Presence of increased mitotic activity and necrosis (as well as so-called cleaved nuclei) required for diagnosis of poorly differentiated thyroid carcinoma (see later in chapter)
- Cellularity and cytologic appearance vary from tumor to tumor and even within the same tumor:
 - Tendency to demonstrate greater cellularity as compared to follicular adenoma
 - Lesional cells generally uniform with defined cell borders
 - Nuclei are:
 - Regularly shaped (round to oval), often aligned along basal aspect of cell
 - Small to medium in size, hyperchromatic with coarse nuclear chromatin
 - Absent to inconspicuous nucleoli
 - Variable amount of cytoplasm
 - Cytoplasm may be amphophilic, eosinophilic, oncocyctic, and/or clear

Fig. 28-27. Follicular carcinoma with vascular invasion.

In these examples the vascular spaces are either in the capsule or beyond the capsule. **A** and **B**, Tumor in endothelial lined vascular spaces (*arrowheads*) with thrombus formation (*arrows*). **C** and **D**, Tumor with direct extension/protrusion into endothelial lined blood vessel with thrombus formation (*arrows*).

- In presence of oncocytic cytoplasmic changes, nuclei may be enlarged with prominent nucleoli but retain uniformity in shape and coarse nuclear chromatin.
- Nuclear pleomorphism may be present:
 - Endocrine atypia characterized by markedly enlarged and hyperchromatic nuclei may be focally identified.
- Colloid filled follicles are generally readily apparent but in some instances may be difficult to identify:
 - Periodic acid Schiff (PAS) stains of assistance in delineating presence of colloid
- Mitotic figures can be seen but are usually uncommon:
 - Increased mitotic activity may be present in more widely invasive follicular carcinoma.
- Necrosis typically absent
- Intratumoral vascularity in form of delicate capillaries may be present but often inconspicuous by routine light microscopy.
- Retrogressive changes often seen in adenomatoid nodules not commonly present but may be seen in particular follicular carcinomas with predominance of cells with oncocytic cytoplasmic changes
- Immunohistochemistry:
 - In general, immunohistochemical staining unnecessary in diagnosis and differential diagnosis of follicular epithelial-derived tumor, including follicular carcinoma
 - Thyroglobulin most useful stain:
 - Reactivity in cytoplasm and luminal colloid
 - TTF-1 (nuclear), PAX8 (nuclear) positive
 - Cytokeratins, including AE1/AE3, CAM 5.2, CK7:
 - CK20 negative

Fig. 28-28. Follicular carcinoma with vascular invasion.

A and **B**, Tumor cells invade vascular spaces covered by endothelial cell layer identified over bulging tumor nests (endothelialization). **C**, CD31 immunoreactivity assists in confirming the presence of the endothelial cells.

- Calcitonin, synaptophysin, chromogranin negative
- CD56 may be positive.
- Cytogenetics and molecular genetics:
 - *RAS* mutations
 - 30% to 50%
 - *PAX8/PPAR γ* rearrangement:
 - Occurs in approximately 20% to 50% of follicular carcinomas
 - Strong evidence of malignancy
 - Reported in approximately 8% of follicular adenomas

Invasion in Follicular Carcinoma

- Diagnosis of follicular carcinoma predicated on invasive growth, including:
 - Capsular invasion
 - Vascular invasion
 - Invasion into adjacent thyroid parenchyma and/or outside the thyroid gland (extrathyroidal extension)
- Tumors showing vascular invasion frequently also show capsule invasion.
- Although presence of invasive growth conceptually appears to be straightforward, there are discrepancies among pathologists, including experts in thyroid pathology, as to which microscopic findings constitute capsular invasion and/or angioinvasion.
- Owing to formation of fibrous tissue along advancing edge of tumor, rarely identify direct contact between lesional cells and adjacent normal thyroid parenchyma
- Certainly, diagnosis of follicular carcinoma includes presence of metastatic tumor but in general uncommon for encapsulated thyroid follicular neoplasm to metastasize in absence of invasive growth

Capsular Invasion

- Extent of capsular invasion source of contention:
 - Some authorities believe that any degree of extension of tumor into capsule qualifies as capsular invasion:
 - Too low a threshold
 - Not considered diagnostic as invasion
 - Partial invasion of capsule:
 - Owing to reported absence of recurrence or metastasis many authorities (although not all) do not accept partial capsular invasion as diagnostic for carcinoma.
 - Most authorities require penetration of entire thickness of capsule to be regarded as unequivocal evidence of capsular invasion.
- Elastic stains may be helpful in determining whether capsular invasion has occurred.
- Problematic features relative to diagnostic interpretation include:

Fig. 28-29. Vascular invasion.

The strict criteria proposed for vascular invasion requiring tumor cells invading through vessel wall and endothelium with thrombus adherent to intravascular tumor may be too strict. **A** through **F**, Examples of tumor lacking the proposed strict criteria for vascular invasion but nonetheless show tumor within vascular spaces that should be considered as significant representing vascular invasion.

Fig. 28-30. Separate but histologically similar nodule(s).

The presence of tumor nodules separate from (but histologically similar to) the main mass within the fibrous capsule (or beyond) with rounded appearance/edges suggests vascular invasion. However, there is no clear-cut identification of endothelial cells by light microscopy and/or immunohistochemical staining for endothelial markers (e.g., CD31) and no associated thrombus formation. Multiple deeper sections fail to show continuity of the nodules to the main mass so that capsular invasion cannot be confirmed. Assuming there are no other findings that might be diagnostic for malignancy, in such cases a diagnosis of a follicular adenoma with atypical features can be considered with the caveat that a follicular carcinoma cannot be excluded.

- Irregular contour(s) of the tumor:
 - May be caused by presence of thick-walled vascular spaces in capsule
- Tangential sectioning or folding of capsule at edge of section
- Changes secondary to prior fine-needle aspiration biopsy, including capsular pseudoinvasion:
 - May take the form of a needle tract in which there is a linear-appearing “bud” into fibrous capsule

Fig. 28-31. Metastatic follicular carcinoma.

Follicular thyroid carcinoma typically metastasizes by hematogenous routes and may include metastatic tumor to (A) liver and (B) bone. C, Thyroglobulin immunoreactivity in the lesional cells confirms thyroid follicular cell origin.

- Low magnification appearance suggests capsular invasion, but at higher magnification follicular epithelium does not violate capsule.
- Needle tract composed of dense fibrosis as well as chronic inflammatory cells infiltrate, including macrophages and giant cells with or without hemorrhage (recent and remote, latter in form of hemosiderin deposition); cholesterol granuloma formation may be present
- Epithelial displacement or entrapment:
 - May take form of small clusters of follicular cells within capsule
- Separate nodule lying immediately outside the capsule of main tumor mass:
 - In this setting, serial sections to determine whether there is a connection present or not is indicated
 - Presence of continuity between main mass and nodule outside the capsule would be indicative of invasion and diagnostic for a carcinoma.
 - Absence of any connection does not exclude a diagnosis of carcinoma.
 - May be indicative of multiple adenomatoid nodules
 - Important to try to determine if separate nodule(s) is or is not histologically similar to main lesion:
 - Histologic similarity with or without direct continuity may be indicative of invasion.
 - Histologic dissimilarity may be indicative of separate adenomatoid nodule(s).
- As nodal metastasis is rare in follicular carcinoma, invaded vascular space are not lymphatics
- Vascular space must lie within capsule or beyond the capsule:
 - Involvement of vascular space within substance of tumor does not qualify as vascular invasion.
- Criteria for diagnosing vascular invasion:
 - Presence of tumor within endothelial-lined space:
 - Tumor adherent to wall lined by identifiable endothelial cells with or without associated thrombus formation
 - Tumor cells protruding into vascular space with endothelial layer identified over bulging tumor nests (endothelialization):
 - Includes vessels within capsule and/or outside capsule
 - Tumor cells within vessel lumen not adherent to wall and not endothelialized still qualifies as vascular invasion if there is thrombus formation
- Minimal requirements for clinically meaningful vascular invasion currently point of controversy:
 - Historically, presence of endothelialized tumor alone has been minimal criterion to identify vascular space invasion, a finding supported in literature.
 - More recently stricter criteria proposed for “significant” vascular invasion requiring both of the following findings:
 - Tumor cells invade through vessel wall and endothelium.
 - Thrombus adherent to intravascular tumor:
 - Application of rigid criteria felt to predict distant metastasis in thyroid carcinoma especially well-differentiated thyroid carcinoma
 - Risk of metastasis when strict criteria not fulfilled is not entirely absent:
 - Strict criteria requiring tumor cells invading through vessel wall and endothelium with thrombus adherent to intravascular tumor may be too strict.
 - Presence of tumor cells protruding into vascular space with endothelial layer identified over bulging tumor nests but without obvious thrombus represents “organization” of a tumor thrombus and is still considered significant.
- Problematic features relative to diagnostic interpretation of VI include:
 - Presence of tumor within fibrous capsule conforming to contour of a blood vessel (rounded edges) suggests but not definitively diagnostic for vascular invasion:
 - Special stains (e.g., CD31) of limited to no utility as tumor may obscure identification of endothelial cells

Tissue Sectioning

- In a follicular neoplasm with worrisome features (i.e., thickly encapsulated, high cellularity with increased mitotic figures and necrosis) but initial sections lack definitive evidence for a diagnosis of carcinoma, most critical issue is adequate and appropriate sectioning of tumor to evaluate the tumor-capsule-thyroid parenchymal interface for evidence of invasive growth.
- No set criteria for number of sections required for adequate histologic evaluation:
 - Guideline to number of sections considered adequate to exclude presence of invasion is:
 - For tumor measuring <6 cm = submit the entire tumor
 - For tumor measuring 6 cm = submit at least 10 blocks
 - For tumor measuring >6 cm = submit one additional block per centimeter of tumor

Vascular Invasion (VI)

- Represents more reliable feature of malignancy than capsular invasion

- Tumor cells “floating” within space not adherent to vessel, without endothelialization, and without thrombus formation do not represent vascular invasion:
 - Represent artifactual placement within vessel lumen
- Tumor cells in capsule associated with artifactual retraction in tissue suggesting vascular space but lacking identifiable endothelial cells is not diagnostic for vascular invasion.
- Tumor cells surrounding vessels or slightly pushing against wall without protrusion into lumen is not diagnostic for vascular invasion.
- Presence of papillary endothelial hyperplasia (Masson tumor-like reaction):
 - May suggest presence of vascular invasion
 - May be associated with dilated vascular spaces and intravascular organized thrombus
 - Reactive phenomenon secondary to prior fine-needle aspiration biopsy
 - Temporal sequence from FNAB to surgical removal important factor in interpretation

Special Stains in Evaluation for Vascular Invasion

- Histochemistry:
 - Elastic tissue stains or trichrome may be helpful but because a continuous smooth muscle layer may not be present they usually are of only limited assistance.
- Immunohistochemistry:
 - Stains for endothelial markers including Factor VIII-related antigen, CD31, CD34, Fli1 (nuclear), ERG (nuclear) may assist confirming presence or absence of tumor cells within endothelial cell-lined space.

Classification of Follicular Carcinoma

- Traditional classification of follicular carcinoma includes two categories:
 - Minimally invasive follicular carcinoma
 - Widely invasive follicular carcinoma
- Based on extent of invasion and biologic behavior an expanded classification can be used, including:
 - Follicular carcinoma with capsular invasion only
 - Follicular carcinoma with limited vascular invasion, including less than four vascular spaces
 - Follicular carcinoma with extensive vascular invasion, including four or more vascular spaces (also referred to as moderately invasive follicular carcinoma)
 - Widely invasive follicular carcinoma

Minimally Invasive Follicular Carcinoma

Definition: Encapsulated follicular epithelial neoplasm histologically showing limited evidence of invasion and lacking features of papillary thyroid carcinoma.

Synonyms: Encapsulated type of follicular carcinoma; low-grade follicular carcinoma

Pathology

Gross

- Essentially similar to that of follicular adenoma

Histology

- Within this category, tumors may be further subdivided on basis of whether there is:
 - Capsular invasion only
 - Limited vascular invasion (less than four vascular spaces)
 - Extensive vascular invasion (four or more vascular spaces)

Differential Diagnosis

- Primarily but not exclusively follicular adenoma
- Adenomatoid nodule(s)
- Papillary thyroid carcinoma
- Medullary thyroid carcinoma

Treatment and Prognosis

- Treatment options include conservative versus more aggressive radical approaches:
 - Conservative therapy includes limited resection (lobectomy or subtotal thyroidectomy) without radioactive iodine therapy:
 - Can be used in presence of low-risk patients, including:
 - Females ≤ 50 years; men ≤ 40 years
 - Tumors less than 5 cm in greatest dimension
 - No distant metastases
 - Radical therapeutic intervention includes total thyroidectomy followed by administration of radioactive iodine:
 - Used in presence of high-risk patients, including:
 - Females > 50 years; men > 40 years
 - Tumors greater than 5 cm in greatest dimension
 - Presence of distant metastases
 - Some authorities would argue that any evidence of VI even less than 4 vascular spaces potentially confers aggressive behavior requiring more aggressive (radical) management.
- Prognosis considered excellent but varies depending on invasive component:
 - Follicular carcinoma with capsular invasion only:

- Essentially no risk of distant metastasis
- Very low to no risk of mortality
- Follicular carcinoma with limited vascular invasion (less than four vascular spaces):
 - Low risk of distant metastasis (approximately 5%):
 - If occurs may do so years following diagnosis
 - Risk of death less than 5%
- Follicular carcinoma with extensive vascular invasion (four or more vascular spaces):
 - Distant metastasis may occur.
 - Higher risk of mortality

Widely Invasive Follicular Carcinoma

Definition: Follicular epithelial neoplasm with widespread invasion (grossly and/or histologically) of thyroid parenchyma, vascular invasion, and/or extrathyroidal invasion but lacking features of papillary thyroid carcinoma:

- Often tumor capsule not present
- Capsule may be identified with obvious complete transgression by tumor.

Clinical

- Much less common than minimally invasive counterpart
- Tend to occur in patients slightly older than those with minimally invasive follicular carcinoma

Pathology

Gross

- Fleshy, solid mass usually measuring greater than 4 cm and may be as large as 10 cm
- Extensive invasive growth can be seen.
- Yellow to red-pink, tan-brown or orange
- Central fibrosis may be seen but irregular fibrosis and cyst formation are uncommon.

Histology

- Less diagnostic dilemma with less subjectivity as compared to minimally invasive follicular carcinoma
- Clear-cut invasion beyond capsular delimitation of tumor with extension into adjacent thyroid parenchyma:
 - Owing to extensive invasion a capsule may not be readily identifiable.
- Vascular invasion readily identified often into medium and large caliber-sized vascular spaces
- Tend to:
 - Show solid or trabecular growth patterns
 - Be hypercellular with nuclear hyperchromasia

Differential Diagnosis

- Papillary thyroid carcinoma
- Poorly differentiated thyroid carcinoma
- Medullary thyroid carcinoma

Treatment and Prognosis

- Aggressive management indicated including total thyroidectomy and postoperative radioactive iodine therapy
- Prognosis varies but generally considered poor:
 - Commonly recur and metastasize:
 - Metastatic rates from 30% to 70%
 - Hematogenously metastasize to bones, lungs, and brain
 - Cutaneous metastasis also occurs.
 - Metastatic disease may be identified at initial presentation.
 - Metastatic tumor treated with radioactive iodine therapy, which may offer long-term palliation but not a cure.
 - Metastatic foci are histologically similar to primary tumor and may appear bland, lacking cytologic atypia.
 - Mortality rate of approximately 50%
 - Adverse prognostic factors include:
 - Presence of extrathyroidal extension into adjacent soft tissues
 - Presence of distant metastasis
 - Lymph node metastasis in follicular carcinoma:
 - Exceedingly rare
 - Many cases reported with nodal metastasis likely were variants of papillary thyroid carcinoma
 - In general nodal metastasis in association with thyroid carcinoma confers a diagnosis of papillary thyroid carcinoma:
 - Exception is in association with follicular carcinoma, oncocytic type, which may metastasize to lymph nodes in 5% to 10% of cases

Follicular Carcinoma, Oncocytic Type (Figs. 28-32 and 28-33)

Definition: Follicular epithelial cell-derived neoplasm exclusively or predominantly (at least 75%) composed of cells with prominent granular eosinophilic cytoplasm (rich in mitochondria) with evidence of invasion but without diagnostic features for papillary thyroid carcinoma:

- Similar to nononcocytic follicular carcinomas; classification includes low-grade (minimally invasive) and widely invasive depending on extent of invasion
- Simply because a tumor has oncocytic cells does not correlate to an aggressive neoplasm; however, higher proportion of solitary encapsulated oncocytic follicular tumors are invasive and therefore

Fig. 28-32. Follicular carcinoma, oncocytic type.

Large circumscribed thyroid tumor characterized by orange color. Microscopically, invasive growth was present.

malignant as compared to solitary encapsulated nononcocytic follicular tumors.

- Whether follicular carcinoma, oncocytic type is a histologic variant of conventional follicular carcinoma or a distinct type of follicular carcinoma remains debatable:
 - Similar pathologic features, aside for presence of oncocytes, support inclusion as variant of conventional follicular carcinoma
 - Differences in biologic behavior and natural history support distinct tumor type

Synonyms: Hürthle cell carcinoma, oncocytic follicular carcinoma, oxyphilic cell carcinoma

Clinical

- More common in women than in men; tends to occur in patients approximately 10 years older than those with follicular adenoma, oncocytic type

Fig. 28-33. Follicular carcinoma, oncocytic type.

A, Extensive capsular invasion by a tumor with solid growth. **B**, At higher magnification the cells show oncocytic cytoplasmic changes, enlarged nuclei with prominent nucleoli, and areas of necrosis (*bottom*). **C**, Focal follicular differentiation in the form of colloid-filled follicles are seen (*arrowheads*) as well as increased mitotic activity (*arrows*) and necrosis (*right*). **D**, Thyroglobulin reactivity.

- As a group follicular carcinomas with oncocytic cells tend to:
 - Occur in older patients than adenomas (approximately 1 decade older)
 - Be larger tumors (approximately 2.0 cm larger)
 - Such features often associated with higher frequency of malignancy as compared to nononcocytic follicular neoplasms.
- Clinical and radiographic features are similar to other follicular carcinomas:
 - Painless thyroid nodule
 - Most are solitary; rarely may be multifocal or bilateral

Pathology

Fine-Needle Aspiration Biopsy

- Cytology essentially similar to follicular adenoma with oncocytic cells
- Smears or aspirates are dominated by enlarged oval to polygonal cells, often in sheets, that have abundant, granular-appearing cytoplasm.
- Due to the oncocytic cytoplasm, there is nuclear enlargement:
 - Nuclei are round to oval and eccentrically located
 - Binucleated cells can be seen.
 - In contrast to its benign counterpart, in follicular carcinoma with oncocytic cells there may be greater nuclear enlargement and increased nuclear pleomorphism, but these findings are not diagnostic for a malignancy.
 - Prominent round, eosinophilic nucleoli are seen.
- Colloid is minimal to absent.

Gross

- Macroscopic appearance is similar to their benign counterparts, although carcinomas tend to be larger than adenomas.

Histology

- Findings similar to follicular adenoma, oncocytic type except that invasion is present:
 - Criteria identical to those described in conventional follicular carcinoma including capsular and/or vascular invasion (see previous)
 - Classification includes minimally and widely invasive categories.
- Histologic features that may be different from follicular adenomas with oncocytic cells include:
 - Thicker capsule
 - Greater degree of solid or trabecular growth
 - Increased nuclear-to-cytoplasmic ratio
 - Presence of increased mitotic activity
 - Presence of necrosis (individual cell or confluent areas)
- Colloid:
 - May be readily apparent or limited in extent

- May calcify including concentric laminations, suggesting presence of psammoma bodies and a possible diagnosis of papillary thyroid carcinoma:
 - Typically located within lumens, not usual location in papillary thyroid carcinomas
 - Cytomorphologic (i.e., nuclear) features not those of papillary thyroid carcinoma
- Oncocytic cells owing to oxygen-sensitive nature of mitochondria more readily undergo retrogressive changes either spontaneously or following traumatic event such as post-fine-needle aspiration biopsy; such alterations may include:
 - Infarction
 - Necrosis
 - Hemorrhage (recent and remote in form of hemosiderin-laden macrophages)
 - Papillary architecture
 - Cyst formation
 - Fibrosis
 - Calcifications
- Histochemistry:
 - Stains for mitochondria may be positive and include:
 - Phosphotungstic acid hematoxylin (PTAH): red staining
 - Novelli stain: dark purple staining
- Immunohistochemistry:
 - Cytokeratin, thyroglobulin, and TTF-1 positive:
 - Thyroglobulin reactivity less intense than in nononcocytic follicular cells
 - CK14 reported as selective marker for thyroid oncocytic cells
 - Chromogranin, synaptophysin, and calcitonin negative
- Electron microscopy:
 - Oncocytic cells are packed with mitochondria.
 - Mitochondrial abnormalities can be seen including quantitative and qualitative (size, shape, content) changes.
- Cytogenetics and molecular genetics:
 - *RAS* mutation in 12% to 25%
 - *PAX8/PPAR γ* rearrangement in 27%:
 - Most with follicular architecture
 - *RET/PTC* rearrangement in 38%:
 - All with solid pattern of growth
 - Identification of *RET/PTC* using highly sensitive methods possibly reflecting very low rearrangement level disputes this finding
 - Other studies failed to identify *RET/PTC* in oncocytic follicular tumors.
 - *GRIM-19* mutation
 - *TERT* C228T promoter mutation detected (in widely and minimally invasive tumors)
 - Identification of aneuploidy in an oncocytic follicular neoplasm does not differentiate an oncocytic follicular adenoma from an oncocytic

follicular carcinoma because both tumor types may show aneuploid cell populations.

- PIK3CA-Akt-mTOR and Wnt/ β -catenin pathways reported to differentiate follicular carcinoma, oncocyctic type from follicular adenoma, oncocyctic type

Differential Diagnosis

- Follicular adenoma, oncocyctic type:
 - Term Hürthle cell neoplasm of uncertain malignant potential ascribed to those tumors showing worrisome but inconclusive features of malignancy, including:
 - Smaller cells with high nuclear-to-cytoplasmic ratio
 - Increased mitotic activity
 - Because these tumors have uniformly followed a benign clinical course this terminology is not advocated, and designation of follicular adenoma, oncocyctic type is preferred.
- Papillary thyroid carcinoma, oncocyctic type
- Medullary thyroid carcinoma, oncocyctic type
- Oncocyctic tumor of parathyroid gland origin

Treatment and Prognosis

- Treatment often includes total thyroidectomy and postoperative radioactive iodine therapy
 - Generally less avidity for uptake of radioactive iodine as compared to nononcocyctic follicular carcinomas
- 5-year mortality rates of 20% to 40%
- Metastases occur to:
 - Lungs and bone
 - Less commonly to regional lymph nodes:
 - Reported 5% to 10% of cases
 - Tends to occur in association with locally advanced disease or distant metastases
 - In presence of nodal metastasis strict criteria must be applied as to exclude diagnosis of papillary thyroid carcinoma, oncocyctic type
 - When spreads to neck occurs usually does so as soft tissue implants rather than to lymph nodes:
 - Likely resulting from spread within venous channels
- Overall mortality rate of 30% to 70%:
 - Worse prognosis as compared to nononcocyctic follicular carcinomas may correlate to:
 - Tend to occur in an older population, which carries a greater risk of aggressive behavior
 - Higher percentage show presence of extrathyroidal extension
 - Higher percentage of tumors recur more often and metastasize more frequently.

- Less avidity to take up radioactive iodine
- Unfavorable prognosis factors may include:
 - Occurrence in men
 - Older age
 - Larger tumor size (≥ 4 cm in greatest dimension)
 - Aneuploidy tumors behave more aggressively than diploid tumors.
- Recent literature reports improvement in survival for follicular carcinoma, oncocyctic type such that survival rates now similar to those of conventional follicular carcinoma
 - Improvement in survival reported for both genders, in patients ≥ 45 years of age, in local and regional disease, and for tumors > 4 cm

Rare Variants of Follicular Carcinoma

- These variants of follicular carcinoma share similar diagnostic criteria, therapeutic interventions, and prognostic indicators as conventional type of follicular carcinoma.
- Follicular carcinoma with clear cells:
 - Defined as follicular epithelial cell-derived neoplasm predominantly composed ($> 75\%$) of cells with clear cytoplasm, evidence of invasion, and absence of nuclear features diagnostic for papillary thyroid carcinoma
 - Presence of cells with clear cytoplasm result of accumulation of glycogen, lipid, and thyroglobulin or ballooning of mitochondria
 - Intracytoplasmic diastase-sensitive, PAS-positive material present indicative of glycogen
 - Clear cells are thyroglobulin and TTF-1 (nuclear) positive.
 - Must be differentiated from metastatic renal cell carcinoma ([Table 28-8](#))
- Follicular carcinoma with signet ring cells:
 - Defined as follicular epithelial cell-derived neoplasm characterized by cells with cytoplasmic vacuoles displacing the nuclei to one side and creating a signet ring appearance, evidence of invasion, and absence of nuclear features diagnostic for papillary thyroid carcinoma
 - Signet ring cells may be focal or diffuse
 - Intracytoplasmic diastase-resistant, PAS-positive but negative mucicarmine and alcian blue staining
 - Cytoplasmic vacuoles are immunoreactive for:
 - Thyroglobulin
 - TTF-1, CK7
 - Lesional cells immunoreactive for:
 - Thyroglobulin, TTF-1 (nuclear), CK7
 - Ultrastructural analysis:

- Cytoplasmic vacuoles shown to be intracellular lumina or dilated vesicles lined by microvilli
- Follicular carcinoma, mucinous variant:
 - Follicular epithelial cell-derived neoplasm with evidence of invasion characterized by presence of abundant extracellular basophilic mucinous material with evidence of invasion
 - Growth patterns of the follicular epithelial proliferation may include microcystic, multicystic, and reticular.
 - Presence of abundant extracellular basophilic mucinous material, which may also be identified within follicular lumens
 - Mucinous material stains for mucicarmine and alcian blue and is diastase-resistant, PAS-positive.
 - In presence of such histologic findings it is imperative to exclude a metastatic mucinous carcinoma from another site, including the gastrointestinal tract, breast, and others.
- Hyalinizing trabecular carcinoma:
 - Considered to be malignant counterpart of hyalinizing trabecular adenoma
 - Some cases reported may in fact represent cribriform-morular variant of papillary thyroid carcinoma that may be associated with familial-adenomatous polyposis (FAP).
 - Measure from 2.5 to 4 cm
 - Histology is identical to that hyalinizing trabecular adenoma except there is capsular and/or vascular invasion.
 - These minimally invasive tumors are biologically low grade.
 - Conservative surgical removal is indicated with close follow-up.
- Tends to occur more frequently in women than in men; occurs in all age groups including pediatric and adolescent but is most common in third through fifth decades of life:
 - Most common thyroid malignant tumor in pre-pubertal age group
- Presentation:
 - Usually asymptomatic (painless) thyroid or neck mass:
 - May or may not be palpable
 - With or without enlargement of regional (cervical) lymph nodes
 - May initially present as lateral neck mass representing nodal metastasis from primary thyroid cancer:
 - Reported in 27% of patients at presentation
 - Primary cancer most often in ipsilateral thyroid lobe
 - Primary cancer may be very small and difficult to detect by clinical and/or radiologic imaging.
 - Metastasis may be predominantly/exclusively cystic and clinically considered to be branchial cleft cyst especially in absence of thyroid mass.
 - Hoarseness and dysphagia may occur:
 - Seen in approximately 20% of patients
 - Indicative of recurrent laryngeal nerve involvement with vocal cord paralysis or tracheal compression
- Any part of the thyroid gland can be affected.
- Radiology
 - Thyroid scan (^{123}I), most often “cold” or hypo-functioning nodules
- Etiology:
 - Radiation exposure:
 - Radiation exposure to neck region is known etiologic factor associated with the development of thyroid cancer in general and PTC in specific
 - Types of radiation exposures include:
 - External beam radiation therapy for treatment of malignant neoplasms and benign conditions:
 - Use of radiation in treatment of benign conditions such as acne relatively common in the earlier part of the twentieth century but essentially abandoned starting the mid-to latter part of twentieth century
 - γ radiation from nuclear reactor accident or nuclear weapon explosion
 - Development of carcinoma is dose dependent (linear correlation) and may arise in a relatively short time period if exposure is large (e.g., following Chernobyl exposure or atomic bomb) or decades later if radiation exposure is less intense (e.g., treatment of acne).

PAPILLARY THYROID CARCINOMA (PTC), USUAL OR CONVENTIONAL TYPE (Figs. 28-34 through 28-44)

Definition: Malignant epithelial cell-derived neoplasm with evidence of follicular cell differentiation defined or diagnosed on basis of characteristic nuclear features:

- Papillary architecture is not a requisite feature for diagnosis.
- Invasive growth is not a requisite feature for diagnosis.

Clinical

- Most common malignant thyroid neoplasm
 - In countries with iodine-sufficient or iodine-excess diets (i.e., nonendemic) makes up to 80% of all thyroid malignant tumors

Fig. 28-34. Papillary thyroid carcinoma, fine-needle aspiration biopsy (FNAB).

A, An epithelial fragment exhibits nuclear crowding and loss of polarity, as well as an intranuclear cytoplasmic inclusion (Diff-Quik). **B**, Nuclear enlargement and tiny vascular core is identified (Diff-Quik). **C**, Nuclei with fine, evenly distributed chromatin with margination of chromatin along the nuclear membrane gives the nuclei in this aspirate the clear, watery appearance that is the cytologic hallmark of papillary carcinoma; irregularities of nuclear contour ("grooves") are apparent (Papanicolaou). **D**, Fragment of epithelium surrounds a refractile psammoma body (Papanicolaou). **E**, Nuclei with fine, evenly distributed chromatin, irregularities in size and shape, and the presence of an intranuclear pseudoinclusion (*arrow*) (H&E). **F**, Many nuclear pseudoinclusions (*arrows*) (H&E). The FNAB diagnosis in all these images was "malignant; papillary thyroid carcinoma (Bethesda VI)." A total thyroidectomy was performed.

Fig. 28-35. Papillary thyroid carcinoma.

The gross appearance of papillary thyroid carcinoma may include **(A)** a predominantly solid tumor with papillary growth; the tumor is only partially encapsulated and toward its left upper outer area loses its circumscription and appears to be invasive (which it was on histologic evaluation); **(B)** encapsulated, predominantly solid but focally cystic tumor; intratumoral fibrosis is grossly apparent; **(C)** predominantly cystic and partly solid with papillary appearance; if metastasis develops from such a tumor, the metastatic foci may also be predominantly or exclusively cystic.

- Thyroid cancer risk following radiation exposure:
 - Highest following radiation at a young age:
 - Highest in children exposed during infancy
 - Decreases with increasing age at treatment
 - Increases with follow-up duration
- Radiation-induced thyroid cancers:
 - Most commonly are PTCs
 - Show solid or mixed solid and follicular growth patterns
 - Primarily have chromosomal rearrangements (e.g., *RET/PTC*) rather than point mutations (e.g., *BRAF*, *RAS*)
- Excess dietary iodine:
 - In areas of endemic goiter, addition of iodine to diet associated with an increase in incidence of PTC and decrease in incidence of follicular carcinoma
- Genetic predisposition:
 - Approximately 5% of PTCs are familial:
 - As component of known hereditary cancer syndrome, including:
 - Familial adenomatous polyposis (FAP): autosomal dominant disease caused by germline mutation of *APC* gene located on 5q21; approximately 1% to 2% of patients develop thyroid carcinoma, primarily PTC and, in particular, cribriform-morular variant (see later in this chapter)
 - Other hereditary cancer syndromes that may develop PTC include: Carney complex, Werner syndrome.
 - Familial PTC development in individuals in families with thyroid cancer but no known hereditary cancer syndrome:
 - PTC occurs within families
 - Reported inheritance as autosomal dominant disorder with incomplete penetrance
 - Tend to be multifocal and arise in association with benign lesions (nodules)
- Pre-existing thyroid disease including:
 - Increase risk of PTC in association with:
 - Adenomatoid nodules and adenoma:
 - Mechanisms not fully understood
 - Chronic lymphocytic (Hashimoto) thyroiditis:
 - More controversial association with mixed evidence weighing for but also against risk for PTC in setting of chronic lymphocytic (Hashimoto) thyroiditis
 - Graves disease:
 - No clear-cut evidence to support Graves disease as risk factor for developing PTC

Fig. 28-36. Papillary thyroid carcinoma, usual type.

A and B, Classic papillary growth pattern including complex arborizing growth and narrow papillae with thin fibrovascular cores. **C and D,** Another example showing complex papillary pattern including narrow and elongated papillae running in parallel (railroad track-like) and fibrovascular stroma.

Pathology

Fine-Needle Aspiration Biopsy

- In contrast to follicular adenoma and follicular carcinoma, cytologic features of PTC are diagnostic by FNAB, making needle aspiration an excellent diagnostic tool.
- Findings include:
 - Cellular aspirates and smears
 - Colloid is scant and may be absent.
 - Cells may be arranged in papillary formations, monolayers, follicles, small or large cell clusters (syncytium-like formations), or individually dispersed.
 - Papillary formations may be sharply outlined with complex branching and central vascular core.
 - Key diagnostic components are nuclear features, which include:
 - Enlargement with irregularities in size and shape
 - Powdery or dusty chromatin pattern:
 - Nuclear clearing “orphan Annie” seen in histologic preparations not found in cytologic preparations
 - Intracellular (pseudo)inclusions
 - Nuclear grooves
 - Nuclear crowding or overlapping
 - Cytoplasm usually abundant and includes pale, vacuolated, or foamy appearance
 - Cytoplasmic features are not of much assistance in diagnosis.
 - Psammoma bodies can be seen and are helpful in the diagnosis.
 - Multinucleated cells can be seen and sometimes are abundant.

Gross

- Most are solid with poor circumscription:
 - May be circumscribed with or without identifiable capsule:

Fig. 28-37. Papillary thyroid carcinoma.

Additional features that can be seen in papillary thyroid carcinoma include **(A and B)** intralesional fibrosis and **(C and D)** multinucleated giant cells identified in the lumens of the lesional follicles.

Fig. 28-38. Papillary thyroid carcinoma.

A and B, Psammoma bodies represent a characteristic feature seen in association with papillary thyroid carcinomas appearing as round, calcified concretions with concentric laminations. Psammoma bodies are felt to represent necrotic tumor cell(s) that form the nidus for deposition of calcium salts.

Fig. 28-38, cont'd

C and **D**, Isolated or “naked” psammoma bodies represent strong evidence for presence of PTC and can be seen in normal thyroid parenchyma felt to represent intrathyroidal spread of PTC. **E**, Electron microscopic depiction of a psammoma body shows the concentric layering of this calcified nidus of tumor. **F**, Mineralization of colloid may simulate the appearance of psammoma bodies; however, in contrast to psammoma bodies there is an absence of concentric laminations and appear in the center of follicles composed of cells lacking diagnostic features for thyroid papillary carcinoma. **G**, Psammoma bodies are not specific for papillary thyroid carcinoma as seen in this example of a psammoma body with concentric laminations located within a follicle composed of cells lacking diagnostic features for thyroid papillary carcinoma.

Fig. 28-39. Papillary thyroid carcinoma.

The diagnosis of papillary thyroid carcinoma (PTC) ultimately hinges on the nuclear features that include **(A and B)** enlarged nuclei with irregularities in size and shape, dispersed to clear-appearing nuclear chromatin, nuclear crowding and overlapping with loss of the basal polarity of the nuclei that randomly are arrayed in all portions of the cell, and nuclear grooves; **(C)** nuclear features diagnostic for PTC but, rather than appearing clear, the nuclear chromatin may be fine and evenly (finely) dispersed; **(D)** in addition to the optically clear-appearing nuclei, the presence of nuclear pseudoinclusions with eosinophilic appearance and distinct outlines or margins (*arrows*) is a very helpful diagnostic but not pathognomonic finding for PTC as they may be seen in lesions other than PTC including but not limited to a **(E)** follicular adenoma (*arrowhead*). In comparison to the nuclear inclusions associated with PTC, there may be artifactual “inclusions” or holes with clear appearance and absence of distinct margination. Such holes (*arrowheads*) may be seen **(F)** in association with nuclei showing diagnostic features for PTC or **(G)** in follicular lesions (e.g., adenomas, nodules) lacking such diagnostic nuclear features in which **(H)** they may be numerous. A diagnosis of PTC should not be predicated solely on pseudoinclusions but on a constellation of nuclear features; arguably the most helpful include the nuclear chromatin features and marked variation in the nuclear contours. Further, holes lacking an eosinophilic appearance and distinct outlines should not be mistaken for the pseudoinclusions associated with PTC.

Fig. 28-39, cont'd

Fig. 28-40. HBME1 reactivity in follicular adenoma.

Immunohistochemical staining—in particular, strong membranous staining for HBME—1 has been reported to support a diagnosis of PTC and differentiate it from other follicular (non-PTC lesions). However, immunohistochemical staining is not sensitive or specific for PTC and can be seen in other lesions including (A) follicular adenoma showing (B) strong membranous HBME1 reactivity.

- Capsule typically absent
- Capsule may be seen in certain variants such as follicular variant.
- May or may not show infiltration into adjacent thyroid parenchyma
- Most confined to thyroid without grossly identifiable extrathyroidal extension, but some may show gross evidence of extension into perithyroidal soft tissues
- Variations in size but most measure from 1 to 3 cm in greatest dimension
- Cut section varies and may include:
 - Tan-white, solid tumors with rubbery to firm consistency
 - Partly or wholly cystic tumors filled with clear to yellow/brown fluid
 - Papillary appearance may be apparent by macroscopic examination.
 - May have gritty consistency owing to presence of psammoma bodies:
 - Extensive foci of calcification or ossification may be present.
- Fibrosis is common finding in and around tumor appearing as white area with firm consistency.

Fig. 28-41. Minimal extrathyroidal extension.

PTC with minimal extrathyroidal extension including invasion into **(A)** perithyroidal adipose tissue and **(B and C)** skeletal muscle.

BOX 28-4 Histomorphologic Features of Papillary Thyroid Carcinoma

Architectural Features

- Growth patterns:
 - Papillary, follicular, solid, trabecular, organoid; multiple growth patterns in a single lesion can occur
 - Elongated or twisted follicles with little colloid
- Other findings:
 - Psammoma bodies (concentric laminations)
 - Intratumoral irregular fibrosis
 - Inspissated colloid (darker-appearing colloid as compared to the surrounding thyroid)

Cytomorphologic Features

- Nuclear alterations:
 - Nuclear enlargement
 - Nuclear irregularities in size and shape of nuclear contour
 - Dispersed (very fine) to optically clear-appearing (“Orphan Annie”) nuclear chromatin
 - Margination of chromatin along the nuclear membrane
 - Loss of nuclear basal polarity with haphazardly arrayed nuclei within the cell
 - Nuclear crowding and overlapping
 - Nuclear grooves
 - Nuclear (pseudo)inclusions

- Multifocal disease is common.
- Can be divided by size and extent of invasion into:
 - Microcarcinoma (occult, minute, or microscopic): <1.0 cm
 - Intrathyroidal: encapsulated; invasive; diffuse; cystic
 - Extrathyroidal (massive)

Histology (Boxes 28-4 and 28-5)

- Includes architectural and cytomorphologic features

Architecture

- Classic example includes presence of papillary growth:
 - Papillae tend to be narrow with thin fibrovascular cores and show complexity in growth with arborization.
 - Papillary growth not required for diagnosis and some variants devoid of papillary architecture entirely composed of a tumor with a follicular growth (see **Follicular Variant** later in this chapter)
 - Parenthetically, papillary growth can be seen in other thyroid lesions, including:
 - Diffuse hyperplasia (Graves disease; dyshormonogenetic goiter)
 - Adenomatoid nodules: as retrogressive change occurring spontaneously or following a traumatic event such as prior fine-needle aspiration biopsy

Fig. 28-42. Metastatic PTC to cervical neck lymph nodes without extranodal extension.

A and B, Nests of tumor without lymph node parenchyma with associated psammoma bodies. **C and D,** Isolated or “naked” psammoma bodies in nodal subcapsular sinuses support a diagnosis of metastatic PTC.

BOX 28-5 Papillary Thyroid Carcinoma: Diagnostic Major and Minor Criteria*

Most Important Criteria (in Order of Importance)

[Brackets contain percentage of cases showing these features.]

1. Cytoplasmic invaginations (pseudoinclusions) into nucleus [25%]
2. Abundant nuclear grooves [100%]
3. Ground glass nuclei [98%]
4. Psammoma bodies [16%]
5. Enlarged overlapping nuclei [99%]
6. Irregularly shaped nuclei [100%]

Less Important Criteria

- Dark staining colloid [86%]
- Irregular contours of follicles [64%]
- Scalloping of colloid [59%]
- Elongated follicles [80%]
- Multinucleated macrophages in lumen of follicles [14%]

*From Lloyd RV, Erickson LA, Casey MB, et al: Observer variation in the diagnosis of follicular variant of papillary thyroid carcinoma, *Am J Surg Pathol* 28:1336-1340, 2004.

- Follicular adenoma: as retrogressive change occurring spontaneously or following a traumatic event such as prior fine-needle aspiration biopsy
- Other growth patterns include:
 - Solid, trabecular, microfollicular, macrofollicular, insular, and cystic:
 - Any of these patterns may be sole pattern seen or multiple admixed patterns can be seen in any one tumor
 - Predominantly solid tumors are those in which solid elements make up nearly all of the neoplasm.
- Follicles often are elongated or twisted in appearance:
 - Extremely variable (but not pathognomonic) feature especially in papillary cancers without a papillary architecture and may be useful in diagnosis at time of frozen section

Fig. 28-43.

A, B, Metastatic PTC to cervical neck lymph nodes with (minimal) extranodal extension. The metastatic foci are present within the node parenchyma (*arrowheads*) with extension of tumor into perinodal soft tissue (*arrows*).

- Tend not to be features seen in follicular adenoma/carcinoma or medullary thyroid carcinoma

Cytomorphology

- Nuclear features are paramount in diagnosis:
 - In presence of diagnostic nuclear features, a diagnosis of PTC can be rendered in absence of invasion (i.e., invasion is not a requisite finding for diagnosis)
 - Nuclear alterations remain constant finding irrespective (with some exceptions) of type of PTC under consideration.
- Diagnosis is predicated on constellation of nuclear alterations and should not be decided on basis of a single alteration as many individual nuclear alterations may be present in lesions that are not PTC.

NOTE: To properly evaluate nuclear features in thyroid lesions well-fixed and thin sections (4 microns) are recommended.

Components of Nuclear Alterations

- Nuclear enlargement:
 - As a general rule, nuclei in papillary carcinoma are always larger (two to three times) than those of normal thyroid follicles, adenomatoid nodules, and follicular tumors (adenomas, carcinomas).
 - Presence of oncocytic cytoplasm may induce nuclear enlargement, suggesting a diagnosis of PTC.
- Irregularities in nuclear contour: Irregularities in size and shape of nuclei are a hallmark finding:
 - Nuclear membrane contour is irregular and may take on many appearances including semi-lunar, crenated, or convoluted.
- Nuclear chromatin, including:
 - Nuclear clearing or dispersion with margination of chromatin along nuclear membrane creating optically clear-appearing nuclei (so-called Orphan Annie eyes nuclei):
 - Represent an artifact of fixation
 - Not identified in frozen sections or fine-needle aspiration
 - Often includes very fine (evenly dispersed) to ground glass appearance
- Nuclear grooves:
 - Discrete longitudinal fold appearing as linear line usually along long axis of nucleus
 - Result from irregularity of nuclear contours
 - By electron microscopy represents deep invagination of nuclear membrane
 - Often used as an essential and diagnostic feature of PTC but not specific or unique to PTC and can be seen in non-neoplastic and other thyroid neoplasms (benign and malignant)
- Nuclear orientation:
 - Loss of basal polarity of nuclei with random dispersion in all portions of cell resulting in crowded and overlapping of nuclei
- Nuclear pseudoinclusions:
 - Formed by cytoplasmic invaginations into nucleus
 - Appear as large, round eosinophilic inclusions with sharp borders
 - If identified, represent reliable but not pathognomonic feature in diagnosis
 - Least common feature:
 - Identified in a minority of cases
 - Absence does not exclude diagnosis.
 - Presence does not ensure diagnosis.
 - Distortional changes in processing may result in intranuclear “bubbles” that simulate appearance of “true” intranuclear pseudoinclusions.

Fig. 28-44. Cystic metastatic papillary thyroid carcinoma.

Cystic metastatic PTC to the lateral cervical neck that clinically suggested a diagnosis of branchial cleft cyst. **A**, At low magnification the cystic neck lesion showed a thin epithelial-lined structure (*top*) with a fibrotic wall including lymphoid cells and lymphoid aggregates. **B**, *Left*, the cyst wall included a single layer of nondescript-appearing epithelium, but (*right*) isolated colloid-filled follicles were focally identified in the cyst wall. **C**, In areas the single cell layer showed nuclei with irregularities in size and shape with an identifiable inclusion (*arrow*). Immunohistochemical staining showed the cells to be reactive for **(D)** thyroglobulin, **(E)** TTF-1 (nuclear), and **(F)** PAX8 (nuclear). Based on the diagnosis of metastatic PTC a thyroidectomy was performed in which an occult focus of PTC was found in the ipsilateral thyroid lobe (not shown).

- To prevent this artifact, proper fixation and thin sections are recommended.
- Nucleoli:
 - When present, nucleoli are located along nuclear membrane but do not play a significant component in diagnosis.
- Cytoplasmic appearance:
 - No specific cytoplasmic changes that assist in diagnosis
 - Certain variants of PTC named according to cytoplasmic appearance, including:
 - Oncocytic PTC, clear cell PTC

Other Histologic Findings in PTC

- Psammoma bodies
 - Round, calcified concretions with concentric lamination
 - Felt to represent necrotic tumor cell(s) that form nidus for deposition of calcium salts
 - Name derived from Greek and means “salt-like”
 - Identified in up to 50% of PTCs
 - Located in tip of papillary stalk but can be found in solid neoplastic component or in the stroma between neoplastic follicles
 - Isolated or “naked” psammoma bodies represent strong evidence for presence of PTC
 - True whether found in normal thyroid (intra-thyroidal spread) from adjacent focus or from other lobe
 - In cervical lymph nodes (metastatic tumor)
 - Not specific for PTC but considered rare in benign thyroid diseases
 - Microcalcifications with an appearance similar to psammoma bodies may be found within follicle lumens but are not diagnostic and should be disregarded:
 - These microcalcifications usually lack concentric laminations seen in psammoma bodies.
- Intratumoral fibrosis
 - Dense fibrosis in and around lesional cells with irregular pattern (variable thickness) common feature of PTC
- Colloid:
 - Colloid in PTC tends to be thicker with more intense eosinophilia on H&E section than colloid of adjacent non-neoplastic thyroid follicles:
 - Weak criteria in diagnosis but in conjunction with other features may be helpful in overall histologic picture and diagnosis of PTC.
 - Additional features that can be seen in association with PTC include presence of:
 - Lymphocytic infiltration
 - Squamous metaplasia
 - Multinucleated giant cells and/or foamy histiocytes present in lumen of lesional follicles or between papillae
 - Can rarely be seen in benign thyroid lesions

- Mitotic figures but are uncommon
- Lymph-vascular invasion
- Multifocality or multicentricity:
 - May represent intraglandular spread/metastasis
 - Based on ancillary testing many of these foci have been shown to demonstrate monoclonality and different RET/PTC profiles supporting concept that they are independent primary tumors.
- Extrathyroidal extension (ETE):
 - When present most often manifests as minimal ETE
 - May occur in association with larger tumors or microcarcinomas (less than 1.0 cm in greatest dimension)

Immunohistochemistry

- Lesional cells are immunoreactive for
 - Thyroglobulin (cytoplasmic and luminal colloid), TTF-1 (nuclear), PAX8 (nuclear):
 - Thyroglobulin staining is diminished to absent in foci of squamous metaplasia.
 - Cytokeratins including AE1/AE3, CAM 5.2, CK7
 - CK20 negative
- Expression of Hectortin 1 (HBME1) (strong membranous staining with apical accentuation), galectin 3, cytokeratin 19, and CITED-1 suggested as differentiating PTC (positive reactivity) from lesions other than PTC:
 - Such stains are not sensitive or specific.
 - Similar staining may be present in normal thyroid follicles, follicular cells in non-neoplastic lesions (e.g., chronic lymphocytic thyroiditis), and benign follicular neoplasms.
- Loss of CD56 reactivity in PTC reported as potential useful marker as retention of CD56 staining is identified in benign thyroid lesions and non-PTC thyroid carcinomas
- Calcitonin, chromogranin, and synaptophysin negative

NOTE: To date, there is no single immunohistochemical marker or panel of immunohistochemical markers that are specific (or diagnostic) for PTC.

Cytogenetics and Molecular Genetics

- RET/PTC rearrangement:
 - Reported in 10% to 30% of PTCs
 - RET/PTC-1 most common followed by RET/PTC-3
 - Frequency higher among:
 - Children and young patients
 - Radiation induced PTCs especially:
 - ◻ Following exposure to radiation fallout from Chernobyl accident

- External radiation received during childhood
- Reported prevalence in PTC highly variable owing to geographic variation and detection methods used
- Not found in follicular neoplasms
- **BRAF** mutations:
 - Reliable marker of PTC
 - V600 *BRAF* mutation
 - Constitutes majority of *BRAF* mutations
 - Found in approximately 45% of PTC
 - Not found in follicular tumors and medullary thyroid carcinoma
 - Virtually diagnostic for PTC
 - Found in classic PTCs, tall cell variant, Warthin tumor-like variant, and oncocytic variant
 - Found in 10% to 15% of follicular variant of PTC
 - Much less frequent in PTCs in children and young patients
 - Prognostic significance
- **RAS** mutation
 - Found in 10% to 15% of PTCs essentially limited to follicular variant
 - *NRAS* codon 61 and *HRAS* codon 61 mutations most common
 - Not unique to PTC found in benign thyroid lesions and other malignant neoplasms

Differential Diagnosis

- Lesions that may have a papillary architecture:
 - Adenomatoid nodules, Graves disease, dyschormonogenetic goiter, others

NOTE: Not all lesions with a papillary architecture are papillary carcinomas, and the absence of a papillary architecture does not exclude a diagnosis of thyroid papillary carcinoma.

- Lymphocytic thyroiditis:
 - Lymphocytic infiltrate may be associated with oncocytic cytoplasmic change, which in turn may be associated with nuclear enlargement and vesicular nuclear chromatin raising concern for a diagnosis of PTC.
 - Despite nuclear enlargement and cleared chromatin, nuclei in lymphocytic thyroiditis remain round with regular contours and coarse nuclear chromatin lacking constellation of nuclear alterations seen in PTC.
- Follicular adenoma, including hyalinizing trabecular adenoma
- Follicular carcinoma
- Medullary thyroid carcinoma

Treatment and Prognosis

- Standard treatment is surgery as well as radioiodine therapy and thyroid hormone therapy for nearly all patients:

- Surgery
 - Extent of surgery may vary from lobectomy to subtotal thyroidectomy to total thyroidectomy.
 - Standard approach for tumors measuring ≥ 1.0 cm is total thyroidectomy, nodal sampling of palpable lymph nodes, and subsequent radioactive iodine ablation (^{131}I).
 - Total thyroidectomy traditionally advocated due to high frequency of tumor multifocality
 - For tumors measuring < 1.0 cm more conservative approach can be taken to include lobectomy and subtotal thyroidectomy; however, recommendations for more aggressive surgical approach have been advocated in presence of smaller foci of PTC, including total thyroidectomy and radioiodine ablation (see Micropapillary Carcinoma).
 - Conservative approach including lobectomy with or without isthmusectomy or subtotal thyroidectomy followed by suppression of thyroid-stimulating hormone secretion seems most reasonable in low-risk patient population (see below):
 - In patients falling into low-risk group, conservative therapeutic approach shown to be as effective with similar outcomes as more aggressive approaches to management
 - Complications of total thyroidectomy may include hypoparathyroidism and vocal cord paralysis.
- Surgical treatment of cervical lymph nodes is subject of debate:
 - In absence of cervical lymph node enlargement, a (modified) neck dissection need not be performed.
 - In face of clinically involved lymph nodes, neck dissection is performed:
 - Central compartment neck dissection:
 - Central compartment nodal metastasis is common with reported incidence of up to 50% in patients with PTC
 - Therapeutic central neck dissection prevents:
 - Sequelae of compression and invasion of critical aerodigestive and neural structures
 - Decreases incidence of lymphatic recurrence
 - May improve survival
 - Benefits of therapeutic central neck dissection widely accepted
 - Role of prophylactic neck dissection in patients with clinically negative node status remains controversial.
 - Lateral neck dissection:
 - Indicated in presence of clinically positive lymph nodes
 - For patients with macroscopically positive lymph nodes, neck dissection is associated

- with statistically significant improvement in disease-specific survival as compared to thyroidectomy alone.
- Modified radical neck dissection with preservation of sternocleidomastoid muscle is performed.
 - Utility in patients with clinically negative node status advocated for patients with significant risk factors for lateral metastasis, including:
 - Presence of extrathyroidal extension
 - Older age
 - Male gender
 - Larger primary tumor size
 - Large metastatic burden in central compartment
- Goals of surgical excision in PTC include:
 - Complete excision of cancer, including involved cervical lymph nodes:
 - Important determinant of outcome
 - Residual metastatic lymph nodes represent most common site of disease persistence/recurrence
 - Permit accurate staging
 - Facilitate postoperative treatment with radioactive iodine
 - Permit accurate long-term surveillance, including:
 - Measurement of serum thyroglobulin:
 - Represents highest sensitivity (95% to 100%) of detection of persistent or recurrent disease
 - Radioiodine whole body scanning
 - Minimize risk of recurrent and metastatic spread
 - Rationale for radioactive iodine (^{131}I) ablation includes:
 - Destruction of all thyroid tissue to include occult foci of carcinoma
 - Facilitation of postablative thyroid scanning to exclude persistent disease
 - Administration of ^{131}I cannot be performed in presence of residual normal thyroid gland; hence desire to perform total thyroidectomy
 - Because normal thyroid would concentrate majority of radioactive iodine, goal of destroying occult foci of carcinoma may not be achieved.
 - Radioactive iodine ablation is generally not administered in low-risk groups (see below) because surgery is considered sufficient.
 - Relapse after initial therapy is highest in first decade and may be associated with increased mortality:
 - Relapses may be delayed for decades (20 to 30 years) after initial diagnosis.
 - Overall recurrence reported in 15% to 35% of patients occurring in:
 - Tumor bed
 - Cervical neck lymph nodes
 - At distant sites
 - Incomplete surgical resection associated with increased risk of recurrence
 - Metastatic spread:
 - Preferentially via lymphatic drainage manifesting as intrathyroidal and/or regional lymph node metastasis
 - Distant (visceral) metastatic disease unusual occurring in 5% to 7% of cases
 - Lung is most common visceral metastatic site.
 - Bone, liver, and brain metastasis may also occur.
 - Prognosis:
 - PTC tends to be biologically indolent with an excellent prognosis:
 - 5-year survival of 96%
 - 10-year survival 93%
 - 20-year survival >90%
 - Prognosis influenced by clinical extent of disease (clinical stage):
 - Stage I: 99.8% 10-year survival
 - Stage IV: approximately 41% 10-year survival
 - Overall mortality rates for thyroid carcinoma is 0.2%:
 - Survival rates measured over 20 years vary per risk group:
 - Low risk: 99% 20-year survival
 - Intermediate risk: 88% 20-year survival
 - High risk: 43% 20-year survival
 - Prognosis in PTC can be categorized as to risk based on established criteria, including:
 - AMES: Age, Metastasis, Extent of primary cancer, and Size (Table 28-9)
 - DAMES: DNA, Age, Metastasis, Extent of primary cancer, and Size
 - GAMES: Grade, Age, Metastasis, Extent of primary cancer, and Size
 - AGES: Age, Grade, Extent of primary cancer, and Size
 - MACIS: Metastases, Age, Completeness of resection, Invasion, Size
 - Prognostic factors associated with PTC include:
 - Age and gender:
 - Mortality increases with age:
 - Patients <40 years generally not associated with death as compared to patients >40 years
 - Women fare better than men:
 - Low-risk group: men ≤40 years of age; women ≤50 years of age
 - High-risk group: men >40 years of age; women >50 years of age
 - Tumor size:
 - Risk of death increases with increasing tumor size.

TABLE 28-9 AMES Risk Assessment Parameters in Well-Differentiated Thyroid Cancer

Parameter	Low Risk	High Risk
Age (A)	Men ≤ 40 years of age; women ≤ 50 years of age	Men > 40 years of age; women > 50 years of age
Metastases (M)	Absent	Present
Extent (E) of primary cancer	Intrathyroidal without ETE Follicular carcinoma, minimally invasive	Presence of ETE Follicular carcinoma, widely invasive
Size (S)	< 5 cm	> 5 cm

ETE, Extrathyroidal extension.

- Tumor recurrence and spread increases when the tumors are large (measuring > 4 to 5 cm).
- Best prognosis seen with tumors ≤ 1.0 to 1.5 cm in diameter
- Staging
 - Extrathyroidal extension (ETE):
 - Represents presence of tumor beyond confines of thyroid gland into adjacent soft tissues
 - One of worst prognostic indicators in thyroid cancer
 - Extrathyroidal extension includes minimal extension and extensive extension.
 - Diagnostic findings for minimal extrathyroid extension include the presence of cancer extending into perithyroidal soft tissues, including infiltration of adipose tissue and skeletal muscle, as well as neurotropism.
 - Diagnostic findings for extensive extrathyroid extension would include the presence of carcinoma well beyond the thyroid gland proper with direct invasion (i.e., not metastasis) into one or more of the following structures: subcutaneous soft tissues; adjacent viscera, including the larynx, trachea, and/or esophagus; the recurrent laryngeal nerve, carotid artery, or mediastinal blood vessels.
 - Microscopic foci of PTC with extrathyroidal extension have outcomes that are better than those tumors with extensive invasion outside the gland.
 - Invasion into adjacent anatomic structures (e.g., trachea, esophagus, other) is an unfavorable prognostic finding associated with decreased survival.
 - Distant metastasis
 - Presence of distant metastasis associated with worse prognosis
 - Site of distant metastasis affects prognosis:
 - Osseous and visceral (other than pulmonary) metastasis represents an ominous prognostic finding.
 - Pulmonary metastasis is not associated with as dire a prognosis as with osseous (or other distant) metastatic disease but is associated with a moderate adverse outcome.
 - Nodal metastasis:
 - In general presence of nodal metastasis has limited impact on survival; however, the presence of extranodal extension (ENE) of tumor into soft tissues adversely affects survival with increased risk of distant metastasis and worse prognosis.
 - Histologically proven angioinvasion may be considered as a sign of an increased tendency toward hematogenous spread and consequent increase in the relative percentage of metastases affecting prognosis negatively.
 - Completeness of surgical excision:
 - Complete excision decreases risk of recurrence.
 - Incomplete excision increases risk of recurrence.
 - Tumor encapsulation:
 - Encapsulated tumors and/or tumors showing limited invasion without ETE are associated with a favorable prognosis.
 - Histology (type and differentiation):
 - Adverse prognosis has been related to cell type and/or growth pattern (e.g., columnar cell, tall cell, solid, hobnail, and diffuse sclerosing variants)
 - Molecular prognostic factors:
 - *BRAF* V600E mutation: conflicting information relative to prognostic import associated with presence of *BRAF* V600E mutation, including:
 - Association with more aggressive disease characteristics including:
 - Extrathyroidal extension, advanced stage at presentation, metastatic disease (locoregional, distant), increased patient-related mortality
 - More aggressive disease characteristics also associated with small size, low-stage tumors, and microcarcinomas

BOX 28-6 Histologic Types of Papillary Thyroid Carcinomas

Variants

- Papillary microcarcinoma
- Encapsulated variant
- Follicular variant
- Macrofollicular variant
- Oncocytic variant
- Clear cell variant
- Solid variant or radiation-induced pediatric variant
- Cribriform-morular variant
- Warthin-like variant
- Diffuse follicular variant

Biologically Aggressive Variants

- Diffuse sclerosing variant
- Tall cell variant
- Columnar cell variant
- Hobnail variant
- Poorly differentiated thyroid carcinoma
- Undifferentiated (anaplastic) thyroid carcinoma

- Alternatively, other publications found no significant or more limited association between presence of *BRAF* V600E with aggressive disease characteristics
- Telomerase reverse transcriptase (TERT) promoter mutations reported to be:
 - An independent prognostic indicator of clinically aggressive tumors correlated with worse outcome and disease-specific mortality in differentiated thyroid cancers, in particular PTC
 - Highly prevalent in advanced thyroid cancers, particularly those harboring *BRAF* or *RAS* mutations
- Other molecular findings that may be predictors of aggressiveness in PTC include *STRN/ALK* fusion and *PIK3CA* gene mutations.

VARIANTS OF PAPILLARY THYROID CARCINOMA

Papillary Microcarcinoma (Figs. 28-45 through 28-48)

Definition: Represents an incidentally identified focus of papillary carcinoma that measures 1.0 cm or less in greatest dimension (Box 28-6).

Synonyms: Papillary microtumor; occult thyroid papillary carcinoma; occult sclerosing thyroid papillary carcinoma; microscopic papillary thyroid carcinoma; latent thyroid papillary carcinoma

Clinical

- Common variant and considered most common variant in United States
- Presentation:

Fig. 28-45. Papillary microcarcinoma.

Gross appearance of an occult sclerotic papillary microcarcinoma measuring less than 1.0 cm discovered incidentally in thyroid gland removed for other reasons. Note its peripheral localization, a common location to find papillary microcarcinomas; in this location minimal extrathyroidal extension may occur.

- Usually an incidental finding in thyroid removed for other reasons or found at autopsy
- May be an occult primary tumor identified following diagnosis of cervical lymph node metastasis
 - Occult carcinomas may be microcarcinomas (measuring <1.0 cm) but may be larger tumors.
- May be identified by ultrasonography:
 - With greater use and more sophisticated techniques, microcarcinomas may be detected.

Pathology

Gross

- When visible, may appear as white to brown, firm nodule with stellate appearance and ill-defined contours to circumscribed and/or encapsulated (partial, complete) with more distinct margins
- May be identified in any portion of thyroid but often located along periphery of involved lobe
- May be multifocal in same lobe and/or in opposite lobe

Histology

- May be nonencapsulated or encapsulated:
 - Nonencapsulated microcarcinomas often sclerotic and invasive
 - In presence of prominent sclerosis a stellate appearance may be identified.
- Nuclear features diagnostic for PTC are present.
- Most show predominant follicular growth pattern, although papillary architecture may be present.
- May be multifocal in same lobe or in opposite lobe:
 - Reported in 30% to 40% of cases

Fig. 28-46. Papillary microcarcinoma.

A, Incidentally identified encapsulated focus with invasion through the capsule into adjacent thyroid parenchyma. **B**, At higher magnification diagnostic nuclear features are present.

Fig. 28-47. Papillary microcarcinoma.

A, Incidentally identified focus of papillary microcarcinoma without associated sclerosis. **B**, At higher magnification diagnostic nuclear features are present.

- Those located at periphery of lobe may or may not have extrathyroidal extension.
- Cytogenetics and molecular genetics:
 - Loss of heterozygosity mutational profiles not different from larger papillary thyroid carcinomas
 - RET/PTC mutation is common.
 - *BRAF* mutations may be identified but not as frequent as in larger tumors.

Treatment and Prognosis

- Diagnosis of papillary microcarcinoma is not, by itself, an indication for additional treatment (i.e., surgery, radioactive iodine).
- May metastasize to regional lymph nodes in approximately 16% of cases
 - Metastatic foci are often microscopic.
 - Distant metastasis may occur but is rare occurrence

- Prognosis:
 - Excellent prognosis in majority of cases
 - Aggressive behavior may be seen in association with some cases, including those with:
 - Extrathyroidal extension (ETE)
 - Multifocality
 - Nodal metastasis with extranodal extension
 - *BRAF* V600E mutation:
 - Conflicting information in literature relative to correlation in *BRAF* mutational status and aggressiveness in papillary microcarcinomas
 - Variably reported from 24% to 63% of cases
 - Molecular-pathologic (MP) scoring system for risk assessment in papillary microcarcinomas (Table 28-10) includes combination of:
 - Histologic findings including:
 - ◻ Superficial tumor location: defined as location immediately adjacent to perithyroid

**Fig. 28-48.**

Left, Papillary microcarcinoma with superficial tumor location lying along the periphery of the thyroid with associated sclerosing tissue but no benign thyroid tissue between tumor and extrathyroid soft tissues. *Right*, Nuclear features diagnostic for PTC.

TABLE 28-10 Molecular-Pathologic Scores in the Validation Cohort of Thyroid Papillary Microcarcinomas and the Risk of More

Variable	Low Risk	Intermediate Risk	High Risk
MP _u score	0 to 2	3	4
MP _w score	7	8 to 10	12
Probability (%) of extrathyroid spread, recurrence or metastasis	0	20	60

From Niemeier LA, et al: *Cancer* 118:2069-2077, 2012.

MP_u, Unweighted molecular-pathologic score; MP_w, weighted molecular-pathologic score; MP score includes *BRAF* status and 3 histopathologic features including superficial tumor location, intraglandular tumor spread/multifocality, and tumor fibrosis.

adipose tissue with no benign thyroid tissue between tumor and extrathyroid soft tissues

- Intraglandular spread or multifocality defined as presence of either ≥ 2 separate tumors or (1) smaller tumor aggregates located close to main tumor separated by layer of normal thyroid parenchyma or tumor cells within lymphatic channels or (2) isolated psammoma bodies located in thyroid stroma outside tumor
- Tumor fibrosis scored as none; 1+ mild fibrosis with presence of few inconspicuous, delicate fibrous areas within or at the periphery of tumor nodule; 2+ moderate/

extensive fibrosis clearly recognizable with multiple fibrotic bands within and at periphery of tumor; fibrotic tumor capsule alone without significant fibrosis within tumor not sufficient to score tumor fibrosis as 2+

- Molecular profile:
 - *BRAF* mutation status
- Unweighted MP scores using sum of above features stratify papillary microcarcinomas as:
 - Low risk = score of 0 to 2 = 0 probability of nodal metastasis
 - Moderate = score of 3 = 20% probability of nodal metastasis
 - High = score of 4 = 60% probability of nodal metastasis
- Additional findings reported relative to papillary microcarcinomas:
 - Tall cell variant of papillary microcarcinoma (see Fig. 28-61 under Tall Cell Variant of PTC) associated with aggressive behavior:
 - 27 cases reported associated with extrathyroidal extension (33%), lymphovascular invasion (15%), multifocality (48%), metastasis to central compartment lymph nodes (30%) or lateral cervical nodes (11%), advanced stage (stage III/IVA) at presentation (36%), and *BRAF* V600E mutation (93%)
 - In contrast, 26 cases of age- and size-matched classic papillary microcarcinomas showed no to low extrathyroidal extension (0%), lymphovascular invasion (4%), central compartment lymph node metastasis (8%), lateral cervical node metastasis (4%), multifocal tumors (39%), *BRAF* V600E mutation (77%), and advanced stage (III/IVA) at presentation (8%).
 - Based on above findings recommendation made to differentiate tall cell variant of papillary microcarcinoma from other types of papillary microcarcinomas
 - Prophylactic central compartment neck dissection in papillary microcarcinomas recommended in men, tumors measuring >5 mm, presence of extrathyroidal extension, presence of lateral lymph node metastasis, and positive *BRAF* V600E mutation
 - Risk of lymph node metastases significantly higher in partially or nonencapsulated papillary microcarcinomas than in encapsulated tumors

Follicular Variant of Papillary Thyroid Carcinoma (FVPTC)

Definition: Characterized by follicular pattern growth with absence of well-formed papillae and diagnosis

Fig. 28-49. Follicular variant of papillary thyroid carcinoma, noninvasive.

A, Encapsulated tumor. **B**, Circumscribed but not encapsulated tumor. In both examples the tumor is noninvasive and entirely composed of a follicular growth pattern without papillae. **C**, Follicular growth with nuclear features diagnostic for PTC including **(D)** inclusions (arrowheads) confirms the diagnosis. The absence of invasion is associated with an indolent behaving tumor and the recent recommendation to rename this neoplasm as “noninvasive follicular tumor [NIFT] with papillary-like features”.

predicated on basis of cells showing nuclear features diagnostic for PTC:

- May be encapsulated or circumscribed but not encapsulated
- May be noninvasive
- May be invasive

Noninvasive FVPTC (Fig. 28-49)

- Arguably among more contentious diagnosis in surgical pathology
- Lack of consensus in diagnosis among experts in thyroid pathology, including:
 - Low interobserver reproducibility
 - No consensus regarding how many florid nuclear atypia there must be or how many atypical nuclei there must be in a follicular lesion to classify it as FVPTC
- Diagnosis fraught with much subjectivity
- Molecular analysis shows presence of:
 - *RAS* mutation and *PAX8/PPAR γ* translocation similar to follicular adenoma/carcinoma rather than *BRAF* mutation or *RET/PTC* translocation identified in PTCs
 - High frequency of aneuploidy
 - Exhibit patterns of chromosomal gains and losses similar to follicular neoplasms (adenoma, carcinoma)
- Identified by The Cancer Genome Atlas (TCGA) Research Network to be among *RAS*-like tumors rather than *BRAF* V600E-like tumors (see [General Considerations](#))
- Overall biologic behavior more similar to follicular adenoma than to carcinoma (papillary or follicular)

- Based on molecular genetics and prognosis nomenclature evolving and in near future may be classified among other RAS-like tumors (follicular adenoma/follicular carcinoma) rather than within spectrum of papillary thyroid carcinoma (*BRAF* V600E-like tumors)
- With above in mind, at present this entity still regarded as papillary thyroid carcinoma and so this is discussed in this portion of the chapter. However, a recent conference on the re-examination of the (noninvasive) FVPTC recommended replacing this terminology with “noninvasive follicular tumor (NIFT) with papillary-like features” reflecting the subjectivity among pathologists in establishing the diagnosis of PTC, its RAS-like molecular profile and its extremely indolent biology not warranting the designation as “cancer.”

Synonym: Lindsay tumor

Clinical

- Common variant representing from 20% to 30% of all PTCs
- Demographics, presentation, laboratory findings essentially similar to the usual type of PTC

Pathology

Gross

- Well circumscribed to overtly encapsulated
- Tend to be solid
- Varying sizes

Histology

- Encapsulated or circumscribed without complete encapsulation:
 - Capsule tends to be thin.
 - Absence of invasive growth
- Follicular growth pattern:
 - Follicles may vary in size and shape.
 - Readily identifiable colloid, which may appear darker than colloid in normal thyroid parenchyma
 - Absence of well-formed papillae
- Despite absence of papillary growth, other architectural features of PTC may be seen, including:
 - Elongated and/or twisted follicles
 - Internal irregular fibrosis
 - Presence of psammoma bodies in interfollicular stroma but less common as compared to more typical PTCs:
- Diagnosis predicated on cytomorphologic (nuclear) features in particular:
 - Nuclear enlargement
 - Variation in nuclear size and shape with irregularities of nuclear contour
 - Identifying nuclear membrane irregularities by emerlin immunohistochemistry may be useful as an adjunct diagnostic tool.

- Above findings:
 - Should be well developed
 - Should be seen in many areas of many sections
 - Should not be diagnostically equivocal and/or very limited in extent
- Presence of so-called “sprinkling sign” characterized by admixture of multiple small cellular dark appearing tumor foci scattered in a background of larger follicles resulting in “sprinkling” appearance.
- No objective criteria for diagnosis:
 - No diagnostic threshold established above which diagnosis of FVPTC can be rendered or below which it should not be rendered
 - Given varying thresholds, there is a wide variation in diagnosis and high interobserver variability in diagnosis among pathologists, including experts in thyroid pathology.
- If findings felt to be sufficient for diagnosis of FVPTC, then entire nodule should be so classified (and measured accordingly) even if significant portions do not show diagnostic nuclear features.
- Immunohistochemistry:
 - Lesional cells are immunoreactive for:
 - Thyroglobulin (cytoplasmic and luminal colloid), TTF-1 (nuclear), PAX8 (nuclear):
 - Cytokeratins including AE1/AE3, CAM 5.2, CK7
 - CK20 negative
 - Expression of HBME1 (strong membranous staining with apical accentuation), galectin 3, cytokeratin 19, and CITED-1 suggested as differentiating PTC (positive reactivity) from lesions other than PTC:
 - Such stains are not sensitive or specific.
 - Similar staining may be present in normal thyroid follicles, follicular cells in non-neoplastic lesions (e.g., chronic lymphocytic thyroiditis), and benign follicular neoplasms.
 - Calcitonin, chromogranin, and synaptophysin negative
- Cytogenetics and molecular biology:
 - *RAS* mutation:
 - Identified by The Cancer Genome Atlas (TCGA) Research Network to be among RAS-like tumors rather than *BRAF* V600E-like tumors, although some noninvasive FVPTC had *BRAF* mutation
 - *PAX8/PPARγ* rearrangements (1% to 5%)
 - Absence of *RET/PTC* translocation and *BRAF* mutation

Differential Diagnosis

- Follicular adenoma
- Follicular carcinoma

Treatment and Prognosis

- Surgical resection is preferred treatment
- Excellent prognosis with biologic behavior akin to that of follicular adenoma
 - Absence of nodal or distant metastasis
 - Purportedly lymph node and/or distant metastasis may occur even in absence of invasion, but generally risk in absence of invasion is essentially zero.
 - Tumors prone to metastasis:
 - Thick capsule
 - Significant intratumoral fibrosis
 - Invasion (capsular and/or vascular invasion)
 - Better classified as invasive FVPTC
 - Invasive FVPTC has potentially more aggressive behavior; see below.

Invasive FVPTC (Fig. 28-50)

Definition: Characterized by follicular pattern growth with absence of well-formed papillae and diagnosis predicated on basis of cells showing nuclear features diagnostic for PTC.

- Similar to encapsulated noninvasive counterpart (clinical, histology and immunohistochemistry) except for:
 - Presence of invasion, including capsular and/or vascular invasion
 - Tendency to show:
 - Greater degree of intratumoral fibrosis
 - Extrathyroidal extension
 - Presence of *BRAF* mutation and *RET/PTC* translocation:
 - Identified by The Cancer Genome Atlas (TCGA) Research Network to be among *BRAF* V600E-like tumors rather than *RAS*-like tumors
 - *RAS* mutation occasionally identified

Differential Diagnosis

- Follicular carcinoma

Treatment and Prognosis

- Surgical resection is preferred treatment.
- Excellent prognosis but in contrast to noninvasive FVPTC:
 - Greater tendency to develop nodal metastasis

Classification of Encapsulated Follicular Tumor

- Classification of an encapsulated follicular tumor showing equivocal cytomorphologic features for papillary thyroid carcinoma or isolated limited foci diagnostic for papillary thyroid carcinoma remains controversial:

Fig. 28-50. Follicular variant of papillary thyroid carcinoma, invasive.

A, The tumor is predominantly circumscribed to encapsulated with an area of grossly evident invasive growth (violation of the capsule) at the superior aspect of the resection specimen. **B,** Histologically the tumor entirely composed of a follicular growth pattern invades through and beyond its capsule. **C,** Nuclear features diagnostic for PTC. The presence of invasion generally confers a more aggressive biologic behavior to the tumor.

- If extent of change is significant/widespread (to date there is no clear definition of what constitutes “significant” or “widespread”), then the diagnosis of encapsulated papillary thyroid carcinoma, follicular variant can be made.
 - If features are equivocal and there is no invasion, then this tumor can be termed as a follicular adenoma (with or without atypical features).
 - If features are equivocal but there is definitive evidence of invasion, then tumor can be diagnosed as carcinoma:
 - In such circumstances specific designation of type of carcinoma (i.e., papillary versus follicular) is academic because treatment should be the same.
 - Depending on one’s level of confidence following designations can be used:
 - Carcinoma, favor thyroid papillary carcinoma, follicular variant
 - Carcinoma, favor follicular carcinoma, minimally invasive
 - Well-differentiated carcinoma, not otherwise specified or well-differentiated (follicular) tumor of uncertain malignant potential
 - Not favored, given no link to defined clinical management, frustrating to clinicians and patients with such tumors
 - As previously indicated, reclassification of follicular variant of PTC is inevitable. A recent recommendation by a panel of expert thyroid pathologists (Nikiforov Y, et al—to be published) is to replace the term (noninvasive) FVPTC with an alternative nomenclature based on the facts that: in contrast to classic and many variants of PTC, this tumor has a RAS-like molecular profile; and given its extremely indolent biologic behavior the designation as “carcinoma” is not warranted. The proposed term recommended by that panel was “noninvasive follicular tumor (NIFT) with papillary-like features” which may be retained or may be slightly altered in the final recommendation.
 - Irrespective of specific designation, in such examples prognosis is excellent.
- At low magnification, bears resemblance to adenomatoid or hyperplastic nodules requiring high magnification to evaluate nuclear morphology
 - Macrofollicular growth predominates:
 - Admixture of smaller (nonmacrofollicles) follicles
 - Readily apparent colloid-filled follicles present
 - A potential hint suggesting diagnosis is presence of cellular foci seen throughout neoplasm in central and peripheral locations:
 - Cellular foci show characteristic nuclear features of PTC (see [Box 28-4](#)).
 - Cells lacking PTC-like nuclei are present, including cells with clear nuclei and coarse chromatin, as well as low cuboidal cells with hyperchromatic nuclei may be identified.
 - Given variably nuclear features as well as presence of abundant colloid, macrophages, macrofollicular follicular cell arrangement, and/or absence of widespread cytologic features associated with papillary carcinoma, erroneous diagnosis of goiter can be rendered on FNAB.
 - Presence of papillae not required for diagnosis but abortive papillary structures can usually be found
 - Treatment and prognosis same as that of conventional PTC:
 - Most behave in indolent manner
 - Few cases associated with aggressive behavior, unresponsive to radioactive iodine therapy and poor prognosis
 - May metastasize including to:
 - Regional lymph nodes:
 - Reported to occur in 20% of cases
 - Histology in metastasis often is similar to primary tumor with a macrofollicular architecture
 - In some reported cases no evidence of invasion in spite of nodal metastatic disease
 - Distantly:
 - 6% of cases
 - Most commonly to lung
 - Other sites may include bone.
 - Rare example reported of anaplastic transformation

Diffuse (Multinodular) Follicular Variant

Macrofollicular Variant ([Fig. 28-51](#))

- Rare variant
- In all regards, essentially similar to follicular variant except:
 - Neoplastic follicles are large (macrofollicles) measuring >200 μ m in diameter.
 - Macrofollicles represent >50% of neoplasm.
- Majority are encapsulated or circumscribed.
- Rare reported aggressive form of PTC
- More common in men than women; tends to occur in younger patients (second to third decades)
- Characterized by diffuse replacement of one lobe or entire thyroid gland that may include:
 - Multiple nodules
 - Diffuse involvement of gland without apparent nodules and/or associated sclerosis

Fig. 28-51. Macrofollicular variant of thyroid papillary carcinoma.

A, At low magnification, the lesion is circumscribed but unencapsulated, and noninvasive with an appearance suggesting a diagnosis of an adenomatoid nodule including enlarged/widened follicles (macrofollicles). **B**, At this magnification the cells lining the macrofollicles appear unremarkable; focally an aborted papillary structure is seen (arrow). **C**, At higher magnification the cells lining the follicles show nuclear features diagnostic for PTC. **D**, Left and right, areas of the tumor show papillary architecture with diagnostic nuclear features. The key to the diagnosis is the nuclear alterations whether papillae are or are not identified.

- Follicular pattern growth predominantly small follicles but may be comprised other growth patterns including:
 - Macrofollicles
 - Solid
 - Trabecular
- Irrespective of growth pattern(s), characteristic nuclear features of PTC present but usually lack sclerosis and psammoma bodies
- Associated with invasive growth, including:
 - Lymph-vascular invasion
 - Extrathyroidal extension with invasion of tracheal cartilage and esophagus
 - Nodal metastasis (approximately 88%)
 - Distant (visceral) metastasis including to lungs (75%) and bone (25%)
- Prognosis is favorable due to younger age of patients and excellent response to radioactive iodine therapy,

although (older) patients reported with more aggressive and fatal outcome.

Oncocytic (Oxyphilic, Hürthle Cell) Variant (Fig. 28-52)

- Rare variant
- Gross:
 - Tumors tend to be circumscribed or encapsulated, measuring from 0.5 to 6 cm in greatest dimension.
 - Consistency varies from soft to fleshy to firm and appear yellow to orange to brown in color.
 - Cystic change can be seen.
- Architecturally, tumors show prominent papillary growth with complex configurations and fibrovascular cores:

Fig. 28-52. Oncocytic papillary thyroid carcinoma.

Oncocytic variants of papillary thyroid carcinoma characterized by cells with brightly eosinophilic, granular cytoplasm and diagnostic nuclear features with (A) papillary growth, (B) follicular growth, and (C) predominantly solid growth with a colloid-filled follicle (arrowhead).

- Other growth patterns may include:
 - Follicular growth (oncocytic follicular variant of PTC)
 - Solid growth
- Characteristic cytomorphologic feature is dominance of cells with an abundant eosinophilic, finely to coarsely granular cytoplasm representing increased cellular mitochondria:
 - Focally, clear cytoplasmic change may be seen.
 - Cells are enlarged but are not twice as tall as they are wide and do not have distinct cell membranes (features of tall cell variant, see later).
- Nuclear alterations are those of PTC:
 - Although not seen in all cases, nuclei may have tendency to localize to apical (“tips”) portion of cell
 - Psammoma bodies may be identified.
- Background chronic lymphocytic (Hashimoto) thyroiditis may be present from one third to more than 85% of cases:
 - When prominent overall features resemble those of Warthin tumor-like variant of PTC (see below)
- Immunohistochemistry:
 - Thyroglobulin, TTF-1, cytokeratin, and vimentin reactivity present
- Cytogenetics and molecular genetics:
 - High prevalence of *BRAF* V600E mutations
 - Frequent *RET/PTC* rearrangements
- Must be differentiated from oncocytic follicular adenomas with papillary hyperplasia, which lack characteristic nuclear features associated with PTC
- May invade into adjacent thyroid parenchyma:
 - Extrathyroidal extension may occur but it is uncommon.
- Treatment and prognosis same as conventional PTC

Warthin-Like Variant (Fig. 28-53)

- Rare variant of PTC showing histologic similarity to salivary gland Warthin tumor
- More common in women than in men (10:1); occur over a wide age range from third to seventh decades with mean patient age in fifth decade
- Fine-needle aspiration biopsy:
 - Cellular smears, mostly in large and small papillary clusters of oncocytic-appearing cells
 - Nuclear grooves and rare nuclear inclusions
 - Lymphoplasmacytic cell background
- Tend to be circumscribed and solid but (central) cystic change may be present
- Overlapping features with oncocytic variant of PTC of which it may be considered a subvariant
- Histologic findings include:
 - Papillary architecture with papillae lined by cells with eosinophilic granular (oncocytic) cytoplasm
 - Characteristic nuclear features of PTC

Fig. 28-53. Warthin-like variant of papillary thyroid carcinoma.

A, This thyroid tumor is characterized by similar features to parotid gland Warthin tumor (also referred to as papillary cystadenoma lymphomatosum), including cyst formation, papillary architecture, and presence of associated lymphoid infiltrate; note the presence of chronic lymphocytic (Hashimoto) thyroiditis in the adjacent thyroid parenchyma (*upper right*). **B,** Papillae are lined by cells with eosinophilic cytoplasm with a dense lymphoid infiltrate in the cores of the papillae. **C,** At high magnification the cells show eosinophilic granular (oncocyctic) cytoplasm, characteristic nuclear features of PTC including intranuclear inclusion (*arrowhead*), and a lymphoplasmacytic cells infiltrate in the core of the papillae.

- Lymphoplasmacytic cells infiltrate in core of papillae:
 - Admixture of T- and B-cells
 - Germinal centers may be present.
- Often occurs in background of chronic lymphocytic (Hashimoto) thyroiditis
- Cytogenetics and molecular genetics:
 - *BRAF* mutations
 - *RET/PTC* translocation
- Treatment and prognosis similar to conventional PTC:
 - Generally good prognosis but nodal metastasis and extrathyroidal extension may be identified
- Rare reports of dedifferentiated and/or anaplastic transformation

Clear Cell Variant (Fig. 28-54)

- Histologic variant in which predominant cell type (>50%) has clear-appearing cytoplasm and nuclear features diagnostic for PTC:
 - Other than distinct clear cell features, architecture and nuclear morphology are those of the conventional PTC
 - Presence of clear cytoplasm primarily due to accumulation of glycogen (intracytoplasmic diastase-resistant, PAS-positive) but may also be due to lipid, thyroglobulin, and distended mitochondria
 - Cells with oncocyctic cytoplasm may be present but represent minor component.

Fig. 28-54. Clear cell variant of PTC.

A, Papillary thyroid carcinoma with clear cells in which cells with distinct clear-appearing cytoplasm show nuclear morphology diagnostic for PTC. **B**, In association with the clear cells (lower) there are cells with oncocytic cytoplasm.

- May require immunohistochemistry to confirm follicular epithelial, cell origin, including:
 - Thyroglobulin, TTF-1 (nuclear), PAX8 (nuclear) reactivity
 - Calcitonin, synaptophysin, and chromogranin negative (differentiates from medullary thyroid carcinoma, clear cell variant)
 - CD10, renal cell carcinoma antibody, and PAX2, PAX8, CAIX negative (differentiates from metastatic renal cell carcinoma)
 - PAX8 (nuclear) reactivity not a discriminator between thyroid follicular cell origin and renal cell carcinoma because both are reactive for this marker
- Treatment and prognosis similar to those of conventional PTC

Fig. 28-55. PTC with fasciitis-like or fibromatosis-like stromal component.

A, PTC component includes anastomosing cords and tubules set in a spindle-shaped cellular proliferation with fibromyxoid stroma. **B**, At higher magnification the follicles include cells with nuclear features diagnostic for PTC, and adjacent spindle cells that are cytologically bland.

PTC with Nodular Fasciitis-Like or Fibromatosis-Like Stroma

(Fig. 28-55)

- Unusual histologic variant of PTC characterized by presence of a fasciitis-like or fibromatosis-like stromal component:
 - Confined to thyroid gland and likely represents an exaggerated stromal response to presence of invasive carcinoma
 - Stromal component may be exuberant and obscure diagnostic foci of PTC.
- Stromal component composed of:
 - Spindle-shaped cells with irregular fascicular growth, fibromyxoid stroma, and extravasated red cells

- But may also include:
 - Less dense cellularity with looser arrangement of spindle cells and associated myxoid stroma
 - Keloid-like fibrosis
- Spindle cells:
 - Cytologically bland with vesicular chromatin, small nucleoli, and low nuclear-to-cytoplasmic ratio
 - Mitotic figures may be identified but atypical mitoses not present
 - Immunoreactive for:
 - Vimentin and actins (support myofibroblastic nature of cells)
 - Beta-catenin (nuclear) reported in a single case to date
 - Cytokeratins, thyroglobulin, TTF-1, and PAX8 negative
- PTC component:
 - Arranged in anastomosing cords, tubules, and papillae
 - Nuclear features characteristic for PTC are present.
 - Associated squamous metaplasia may be identified.
- Treatment and prognosis are similar to those of conventional PTC.
- Nodal metastasis may occur and typically includes only carcinomatous component and not nodular fasciitis-like component.
- Differential diagnosis may include:
 - Undifferentiated (anaplastic) thyroid carcinoma
 - Presence of PTC with exuberant spindle cell proliferation may suggest diagnosis of undifferentiated (anaplastic) carcinoma but absence of cytologically high-grade features in spindle cell component of nodular fasciitis-like stroma should allow for differentiation.
 - Reactive fibrosis:
 - PTC component may not be readily apparent, owing to limited sampling or obscuring of neoplastic proliferation by spindle cell proliferation

Solid Variant (Fig. 28-56)

- PTC in which >50% of tumor has solid or trabecular growth
- Occurs in adults as well as in children and may be predominant pattern in very young children, especially those exposed to ionizing radiation:
 - Radiation-induced:
 - Along with diffuse sclerosing variant (see later in this chapter) represents most common growth pattern identified in children following Chernobyl accident
 - Higher radiation doses associated with higher frequency of solid and diffuse

Fig. 28-56. Solid variant of thyroid papillary carcinoma.

A, Solid (diffuse) growth that comprises greater than 50% of the tumor. **B** and **C**, Nuclear features are diagnostic for papillary thyroid carcinoma. In contrast to poorly differentiated thyroid carcinoma, there is an absence of necrosis and increased mitotic activity.

- sclerosing variants as well as histologic features of cancer aggressiveness, including lymph-vascular invasion, intrathyroidal infiltration, multifocality
 - Other growth patterns may be seen in this setting, including follicular and papillary (classic).
- Solid nests may be separated by thin fibrovascular stroma, creating “insular” or nested/organoid pattern of growth:
 - Stromal component may vary from thin fibrous strands to thick fibrous bands.
 - Fibrovascular stroma with separation artifact may be seen in association with insular pattern.
- Follicular and papillary growth patterns can be focally identified:
 - Microfollicles (with or without colloid) as well as larger colloid-filled follicles may be identified.
 - Abortive papillae or well-formed papillae can be seen.
- Nuclear features diagnostic for PTC present
- No increase in mitotic activity and no necrosis
- Immunohistochemical staining includes:
 - Reactivity for thyroglobulin (may be very focal and/or limited in extent), TTF-1 (nuclear), PAX8 (nuclear)
 - Absence of calcitonin, synaptophysin, chromogranin
- Cytogenetics and molecular genetics:
 - Presence of *RET/PTC3* in most pediatric (postradiation exposure) cases but absent in adult patients without radiation exposure
- Differential diagnosis includes:
 - Poorly differentiated thyroid (“insular”) carcinoma (PDTC) (see later in this chapter):
 - Rare tumor type in children, adolescents, and young adults
 - Shares growth patterns with solid variant
 - Diagnosed primarily on basis of increased mitotic activity and presence of tumor necrosis findings not identified in solid variant of PTC
 - Medullary thyroid carcinoma:
 - Absence of colloid-filled follicles
 - Presence of immunoreactivity for calcitonin, synaptophysin, chromogranin
 - Absence of immunoreactivity for thyroglobulin, TTF-1, PAX8
- Prognosis:
 - In adults tends to have more aggressive behavior, including:
 - More frequently associated with distant metastasis
 - Slightly higher mortality rates
 - Post-Chernobyl radiation induced found to be:
 - Associated with higher frequency of lymph node metastases

- Associated with higher frequency of angioinvasion
- Associated with higher frequency of extrathyroidal invasion

Cribiform-Morular Variant (CMV-PTC) (Fig. 28-57)

- Rare variant of PTC representing less than 1 % of all PTCs
- May occur in association with familial adenomatous polyposis (FAP) or independent of FAP
- In setting of FAP:
 - Striking female predominance
 - Mean age at diagnosis in third decade of life; may occur in pediatric ages
 - Tend to be multifocal
 - Thyroid carcinoma may be identified prior to diagnosis of FAP.
 - Patients with CMV-PTC should be referred for colonoscopy and/or genetic evaluation for FAP because up to 40% will prove to have FAP.
 - Patients show germline mutation in adenomatous polyposis coli (*APC*) gene that frequently affects codon 15
- In non-FAP setting:
 - Sporadic occurrence
 - Also tend to occur in young females
 - Solitary lesion
 - Do not carry germline *APC* mutation
 - Frequently have somatic mutation in *APC* gene or in *CTNNB1* gene coding for β -catenin
- Histology:
 - Multiple or solitary circumscribed to encapsulated nodules:
 - Multifocality represents strong indicator of familial disease.
 - Invasion (capsular, vascular) may or may not be present.
 - Characterized by presence of prominent cribriform growth with interspersed squamoid islands referred to as morules
 - Cribriform:
 - Closed packet and fused follicles
 - Typical without identifiable colloid (empty spaces)
 - Morules:
 - May be absent in any given case
 - No evidence of squamous differentiation in form of keratinization and intercellular bridges
 - Additional growth characteristics may include:
 - Papillary architecture
 - Trabecular pattern with associated hyalinization

Fig. 28-57. Cribriform-morular variant of papillary thyroid carcinoma.

A, B, Cribriform growth includes closely packed and/or fused follicles that appear empty without colloid. Papillary growth pattern (*lower left*) may be present. **C,** Tumor cells appear columnar. **D,** Nuclei show nuclear (chromatin) clearing or inclusions appearing homogeneous and lightly eosinophilic and represent biotin-rich inclusions (*arrowheads*). **E,** Lesional cells are strongly TTF1 (nuclear) positive although a morular appearing focus is negative. **F,** Lesional cells (*top left*) show strong β -catenin nuclear and cytoplasmic staining in contrast to the normal (*non-neoplastic*) thyroid cells that show membranous (and not nuclear) staining (*bottom right*).

- Tumor cells may appear columnar or cuboidal:
 - Oncocytic cytoplasmic changes may be present.
- Nuclear features characteristic for PTC present but may only be focally found
- Nuclei show nuclear (chromatin) clearing or inclusions:
 - Appear homogeneous and lightly eosinophilic
 - Represent biotin-rich inclusions
- Psammoma bodies may be identified but are uncommon.
- Immunohistochemistry:
 - Neoplastic cells are:
 - Strongly immunoreactive for cytokeratins and TTF-1 (nuclear)
 - Tend to be focal and weakly thyroglobulin positive
 - β -catenin reactive (strong nuclear and cytoplasmic staining)
 - Normal (non-neoplastic) thyroid cells show membranous staining pattern for β -catenin, which changes to nuclear and cytoplasmic staining in neoplastic cells:
 - β -catenin staining supportive of diagnosis and may prove useful in cases with equivocal diagnostic features in cytologic and/or surgical material
 - In familial cases germline inactivating mutation of *APC* tumor suppressor gene and in sporadic cases somatic *APC* mutations or somatic mutations of *CTNNB1* gene that stabilize β -catenin prevent cytoplasmic degradation and promote accumulation in nuclei
 - Rare example reported with neuroendocrine differentiation including reactivity for synaptophysin and chromogranin but absence of calcitonin
 - Cytogenetics and molecular genetics:
 - *RET/PTC* rearrangement common
 - *BRAF* mutations not identified
 - Prognosis:
 - Nodal metastases occur in up to 20% of patients
 - Survival similar to that of classic PTC
 - Rare example of coexisting poorly differentiated thyroid carcinoma reported
- Generally are large, measuring more than 5 cm
- Often present with extrathyroidal extension
- Tend to disseminate early in disease course with regional lymph node metastasis as well as distant metastasis (particularly to lung)
- Are treated more aggressively than conventional PTC or less aggressive variants of PTC
- Some of tumors included within aggressive variants of PTC have been designated according to a particular cell type (e.g., tall, columnar), whereas others have been designated according to a growth pattern (e.g., insular); fact that these tumors are included within the spectrum of aggressive variants, and treated accordingly, should not be predicated solely on basis of a particular cell type or growth pattern; rather, each tumor should be evaluated as any other papillary carcinoma based on other potential prognostic parameters, including:
 - Patient age, tumor size, and extent of invasion (i.e., the presence or absence of extrathyroidal extension)
- Given tendency for these tumors as a group to be large, they may also have a tendency to have extrathyroidal extension; this finding, perhaps with some additional features associated with these tumors (e.g., older age at presentation), probably play a much more significant role than cell type or growth pattern in predicting aggressiveness of tumor.
- Exception to this would be the undifferentiated (anaplastic) thyroid carcinoma, which by definition is a high-grade, aggressive tumor

BIOLOGICALLY AGGRESSIVE VARIANTS OF PTC

See Box 28-6.

General Considerations

- These variants of PTC:
 - Tend to occur in older-age patients (except for the diffuse sclerosing variant)

Diffuse Sclerosing Variant (DSV)

(Figs. 28-58 and 28-59)

Clinical

- Uncommon variant representing less than 1% to 2% of PTCs
- Occurs more commonly in women than in men; tends to occur in younger age groups typically in second and third decades
- Clinical presentation most often as bilateral goiter or diffuse enlargement of thyroid gland rather than as a single mass; however, some patients may present with a “dominant” nodule with diffuse involvement of single lobe
- Delay in diagnosis may be due to fact that clinical presentation similar to that of chronic thyroiditis, including presence of serum antithyroid antibodies, including antithyroglobulin and antimicrosomal antibodies
- No known etiologic factors:
 - May occur in patients with radiation exposure

Fig. 28-58. Diffuse sclerosing variant of papillary thyroid carcinoma.

A, Diffusely infiltrative tumor with associated sclerosis including solid nests (*left*) as well as tumor nests with associated calcifications and a background of chronic lymphocytic thyroiditis. **B** and **C**, Papillary and solid growth with associated psammoma bodies. **D**, Associated squamoid squamous metaplasia including squamous morules is frequently present. **E**, Lymph-vascular space invasion is another feature commonly identified. Although not illustrated, extrathyroidal extension was present.

Fig. 28-59. Metastatic DSV.

The diffuse sclerosing variant of papillary thyroid carcinoma is associated with an increased incidence of cervical lymph node metastasis. The metastatic foci may include the presence of (numerous) psammoma bodies.

Pathology

Gross

- Bilateral diffusely enlarged thyroid gland or a discrete dominant mass or nodule may be present.
- Irrespective of extent of involvement, mass is firm, tan-white to gray in appearance with ill-defined borders and marked fibrotic change.
 - Identifiable mass may measure 5 cm (or more) in greatest dimension.
- Due to presence of innumerable psammoma bodies (see below), these tumors characteristically have a gritty consistency on cut section.

Histology

- Diffuse involvement of one lobe or entire gland:
 - At low magnification findings include:
 - Readily apparent background of chronic lymphocytic thyroiditis, including germinal centers
 - Dense sclerotic bands
 - Numerous psammoma bodies
- Tumor nests appear solid with associated squamous metaplasia, including squamous morules and islands:
 - Neoplastic cells in foci of squamous metaplasia lack nuclear features of PTC but in other foci diagnostic nuclear features can be found.
 - Innumerable psammoma bodies, including concentric laminations, seen in association with or separate from neoplastic foci
 - Prominent papillary growth with solid areas
- Pronounced fibrosis seen throughout gland
- Lesional cells have propensity to invade the intrathyroidal lymphatic spaces as well as the tendency to show extrathyroidal extension.
- A dense lymphoplasmacytic cell infiltrate is present that may include germinal centers.

- Immunohistochemistry:
 - Lesional cells are variably reactive for:
 - Cells of papillary carcinoma and squamous metaplasia are immunoreactive for thyroglobulin, TTF-1 (nuclear), and cytokeratins
 - Thyroglobulin staining may be weakly positive to absent in squamous metaplastic cells
 - p63 reactivity in squamous metaplastic cells
- Cytogenetics and molecular genetics:
 - *RET/PTC* rearrangement frequently found
 - *BRAF* mutation rarely found

Differential Diagnosis

- Chronic lymphocytic thyroiditis with squamous metaplasia

Treatment and Prognosis

- Total thyroidectomy or near total thyroidectomy is preferred treatment often supplemented by postoperative radioactive iodine therapy.
- Associated with more adverse prognostic findings, including:
 - Higher incidence of extrathyroidal extension
 - High incidence (greater than 80%) of cervical lymph node metastasis (uni- and bilateral)
 - Greater incidence of distant metastasis (approximately 10% to 15%) primarily (but not exclusively) to lung and may also include brain, bone, and liver
 - Shorter periods of disease-free survival
- Despite greater incidence of distant (pulmonary) metastases, mortality rates comparable to those of conventional PTCs possibly owing to ameliorating effects of younger age with:
 - 93% disease-specific survival at 10 years

Tall Cell Variant (TCV)

(Figs. 28-60 through 28-62)

Definition: Type of PTC characterized by presence of tall cells with the following combination of features:

- “Tall” defined as cells whose heights are at least three times greater than their widths:
 - Depending on plane of sectioning cells may be wider than tall
 - Not unique cell type to this variant and may be seen in conventional PTC as well as in other variants—in particular, columnar cell variant (see below)
- Presence of cells with eosinophilic cytoplasm (not quite to level of oncocytes or so-called Hürthle cells)
- Presence of distinct cell borders
- Above finding should be present in at least 50% of a given tumor to be diagnostic for TCV.
 - Those PTCs with tall cells in less than 50% of a given tumor have been referred to as papillary

Fig. 28-60. Tall cell variant of papillary thyroid carcinoma.

A, At low magnification this variant of PTC tends to be extensively infiltrative and characterized by prominent papillary architecture. In addition to papillary architecture, this tumor also shows **(B)** elongated follicles arranged in parallel alignment ("railroad track"-like) and **(C)** follicular growth; **(D)** lesional cells are "tall" (*arrow*), defined as at least three times greater than their widths with eosinophilic cytoplasm (not quite to level of oncocytes or so-called Hürthle cells) and the presence of distinct cell borders. Depending on the plane of sectioning the lesional cells may be wider than tall, emphasizing the other criteria, including slightly eosinophilic cytoplasm and distinct cell borders. **E**, Nuclear features diagnostic for PTC are present, including readily identifiable nuclear inclusions (*arrowheads*).

Fig. 28-61. Tall cell variant of papillary microcarcinoma.

Left, An incidental focus of papillary microcarcinoma is present in association with chronic lymphocytic (Hashimoto) thyroiditis identified in a thyroid gland resected for multinodular goiter. *Right*, At higher magnification the histologic features are those of the tall cell variant of thyroid papillary carcinoma. In general, microscopic foci of PTC do not convey any more aggressive behavior than more usual foci of PTC, but microscopic foci of the tall cell variant are reported as potentially being associated with aggressive biologic behavior.

thyroid carcinoma with tall cell features (see [Treatment and Prognosis](#) below)

Clinical

- Represents up to 10% of all PTCs
- More common in women than men; generally occurs in older age groups (\geq sixth decade of life):
 - May occur but uncommon in pediatric and young adult ages
- Clinical presentation includes asymptomatic or enlarging neck mass.
- Appear as “cold” nodules on thyroid scanning
- Etiology:
 - Unknown

Pathology

Fine-Needle Aspiration Biopsy

- Cytomorphologic features may include presence of papillary fronds, oncocyctic cells with prominent nuclear grooves, and intranuclear cytoplasmic inclusions.
- Multiple inclusions within same nucleus impart a “soap bubble appearance” to nucleus, a finding rarely seen in conventional PTC.

Gross

- Tend to be large, measuring >5 cm in greatest dimension

Fig. 28-62. Oncocyctic variant versus tall cell variant of PTC.

Left, The cells in the oncocyctic variant are not “tall,” have a more intensely eosinophilic cytoplasm, and lack distinct cell membranes. *Right*, Tall cell variant composed of “tall” cells with lightly eosinophilic cytoplasm and distinct cell membranes.

- Extrathyroidal extension may be grossly apparent.

Histology

- Tend to be unencapsulated and infiltrative with prominent papillary architecture:
 - Other growth patterns include trabecular, cord-like, and follicular.
 - Colloid-filled follicles are readily identifiable.
 - Marked fibrosis is present.
 - Another pattern of growth includes markedly elongated follicles arranged in parallel (“railroad track–like”) with minimal colloid content.
- Nuclear features diagnostic for PTC well developed, including:
 - Variation in size and shape
 - Nuclear grooves and pseudoinclusions readily apparent and prominently present
 - However, optically clear nuclear chromatin may not be readily apparent.
- Cytoplasmic features include distinct cell borders and presence of abundant or dense cytoplasmic eosinophilia:
 - Likely due to increased mitochondrial content
 - Less abundant as compared to oncocyctic (so-called Hürthle) cells
- An associated lymphocytic infiltrate not commonly seen but may be present in and around tumor.
- Psammoma bodies may be present but are uncommon.
- Mitotic figures may be present but generally are not significantly increased.
- Extrathyroidal extension and lymph-vascular space invasion not infrequently identified.

- Micropapillary carcinoma, tall cell variant (see Fig. 28-61)
 - Represent PTCs predominantly composed of tall cells measuring less than 1.0 cm in greatest dimension reported to potentially be associated with aggressive biologic behavior (see previous discussion under Micropapillary Carcinoma).
- Immunohistochemistry:
 - Thyroglobulin, TTF-1, and cytokeratin (including CK19) positive
 - Calcitonin, chromogranin, and synaptophysin negative
 - Higher rate of p53 staining as compared to conventional TPC
- Electron microscopy: but not as abundant or showing morphologic abnormality as seen in oncocytic (so-called Hürthle cell) tumors
- Cytogenetics and molecular genetics:
 - *BRAF* V600E mutation very common (approximately 80%)
 - *RET/PTC* translocation (in approximately 33%):
 - Associated with *RET/PTC3*
 - Telomerase reverse transcriptase (*TERT*) promoter mutations identified in TCV
 - Associated with more aggressive behaving thyroid cancers, including:
 - Poorly differentiated thyroid carcinoma
 - Undifferentiated (anaplastic) thyroid carcinoma
 - Greater expression of c-Met
- Higher incidence of cervical lymph node metastasis
- Higher incidence of distant metastasis (lung and bone)
- Higher recurrence rates in neck (approximately 22%) often with invasion into the trachea
- Higher tumor-related mortality rates (approximately 25%)
- Lower 5-year disease-specific survival
- May transform (dedifferentiate) to higher grade malignant neoplasms, including:
 - Spindle cell squamous carcinoma
 - Undifferentiated (anaplastic) carcinoma
- In most reported studies, tall cell variant more aggressive than conventional PTC:
 - Some studies reported no difference in behavior except for presence of extrathyroidal extension.
 - However, TCV without extrathyroidal extension reported to be biologically more aggressive than classical PTC without ETE independent of age, gender, and tumor size
- Papillary thyroid carcinoma with tall cell features:
 - PTCs with 30% to 49% tall cells reported to have:
 - Similar disease-specific survival and distant recurrence-free survival as tall cell variant (i.e., greater than 50% tall cells)
 - Higher rates of high-grade transformation than conventional PTC
 - Poorer outcomes than conventional PTC
 - Based on above findings suggestion made to lower threshold for diagnosis of TCV to 30% of a given tumor
- Microscopic tall cell variant:
 - Reported to be associated with aggressive features at presentation (except in rare pediatric cases), including:
 - Extrathyroidal extension (33%)
 - Lymph-vascular invasion (15%)
 - Multifocality (48%)
 - Metastasis to central compartment and lateral lymph nodes
 - Advanced stage (III/IVa0) (36%)
 - *BRAF* (V600E) mutation (approximately 93%)
 - Based on above findings recommendation made to differentiate microscopic TCV from other papillary microcarcinomas

Differential Diagnosis

- Columnar cell variant of papillary thyroid carcinoma (see below):
 - May be mistaken for tall cell variant given presence of “tall” cells
 - In contrast to tall cell variant, columnar cell variant characterized by:
 - Nuclear stratification
 - Nuclear hyperchromasia
 - Absence of eosinophilic cytoplasm and well-defined cell borders
- Oncocytic variant of papillary thyroid carcinoma
- Warthin-like variant of papillary thyroid carcinoma

Treatment and Prognosis

- Total thyroidectomy or near total thyroidectomy is preferred treatment, often supplemented by radioactive iodine therapy.
- As compared to conventional PTC, this variant has:
 - Tendency to occur in older patients
 - Tendency to be large (>5 cm)
 - Tendency to have extrathyroidal extension
 - Tendency to be refractory to radioactive iodine treatment

Columnar Cell Variant (CCV)

(Figs. 28-63 through 28-68)

Definition: Type of PTC characterized by columnar cells with nuclear stratification:

- Should be present in at least 50% of a given tumor
- Additional patterns can be seen (see below).

Synonym: Hypersecretory variant of PTC

Fig. 28-63. Columnar cell variant.

Columnar cell variant appearing as a large, circumscribed, solid tumor.

Clinical

- Rare tumor type representing less than 1% of all PTCs
- Demographics may vary depending on whether tumors are invasive or encapsulated/noninvasive:
 - Invasive:
 - More common in men than women
 - Most common in sixth decade of life
 - Encapsulated/noninvasive:
 - More common in women than men
 - Most common in sixth decade of life
- Clinical presentation includes asymptomatic or enlarging neck mass.
- Appear as “cold” nodules on thyroid scanning
- Etiology:
 - Unknown

Pathology

Fine-Needle Aspiration Biopsy

- Moderately cellular aspirate of sheets, papillary clusters, and microfollicles
- Cells with oval nuclei and uniform, finely granular chromatin arranged in a pseudostratified manner around well-defined fibrovascular cores
- Absence of intranuclear inclusions or well-defined nuclear grooves in the cells
- Absence to sparse colloid

Gross

- May be large, measuring >5 cm with invasive growth (intra- and extrathyroidal)
 - May be small (<5 cm), encapsulated, and even microscopic

Histology

- May be:
 - Circumscribed to encapsulated without invasion

- Circumscribed to encapsulated with limited invasive growth (capsular or vascular)
- Extensively invasive including into thyroid parenchyma and/or extrathyroidal extension
- Prominent papillary growth but other growth patterns may be seen, including:
 - Follicular, cribriform, and solid
 - Colloid may only focally be seen and can be absent.
 - Another pattern of growth includes markedly elongated follicles with minimal colloid content.
- Cells are tall but are columnar-appearing and have prominent nuclear stratification:
 - Nuclei tend to be elongated and hyperchromatic.
 - In areas of any given tumor, nuclei may show classic features of PTC.
- Cytoplasmic changes may vary and include:
 - Nondescript eosinophilic appearance
 - Clear or vacuolated appearance with subnuclear vacuolization similar to that seen in secretory-type endometrium
- Squamoid foci (morules) and spindle cells with fascicular growth may be present.
- Psammoma bodies may be present but are uncommon.
- Increased mitotic activity can be present; necrosis is generally not found.
- Immunohistochemistry:
 - Thyroglobulin and TTF-1 positive:
 - Marked variability in thyroglobulin reactivity including portions of tumor with intense thyroglobulin reactive, whereas other areas are completely negative or weakly positive, including foci adjacent to intensely thyroglobulin-positive foci
 - Cytokeratin and vimentin positive
 - No immunoreactivity with calcitonin, synaptophysin, and chromogranin
 - CDX2 (nuclear) reactivity purported to be selective marker for CCV, but this finding not substantiated
- Cytogenetics and molecular genetics:
 - *BRAF* V600E mutation (approximately 33%)

Differential Diagnosis

- Tall cell variant of papillary thyroid carcinoma
- Cribriform-morular variant of PTC
- Hyalinizing trabecular adenoma
- Medullary thyroid carcinoma
- Metastatic colonic adenocarcinoma or endometrioid adenocarcinoma

Treatment and Prognosis

- Thyroidectomy preferred treatment and may include:
 - Total thyroidectomy with postoperative radioiodine therapy for larger tumors with extrathyroidal extension

Fig. 28-64. Columnar cell variant.

Columnar cell variant of papillary thyroid carcinoma characterized by **(A and B)** papillary growth and markedly elongated follicles arranged in parallel ("railroad tracks") with minimal but identifiable colloid; **(C and D)** the nuclei are elongated (columnar) and hyperchromatic with stratification lacking the typical features seen in conventional papillary thyroid carcinoma; **(E)** in areas more typical nuclear features of papillary thyroid carcinoma (*upper left*) may be focally identified adjacent to and/or admixed within columnar cells (*lower right*).

Fig. 28-65. Columnar cell variant.

Other findings that are seen in the columnar cell variant include **(A)** follicular growth with nuclear stratification; **(B)** squamoid morules; **(C and D)** cribriform growth devoid of colloid and composed of columnar cells with slightly eosinophilic cytoplasm and nuclear stratification; and **(E)** clear or vacuolated appearance with subnuclear vacuolization similar to features seen in secretory-type endometrium (hence the term hypersecretory variant of CCV).

- Lobectomy or subtotal thyroidectomy for tumor confined to thyroid gland without evidence of extrathyroidal extension
- May metastasize including to:
 - Cervical lymph nodes:
 - Histologic appearance of metastatic foci may include columnar cells, cells with clear-appearing cytoplasm (secretory endometrium-like), and/or cells with classic features of PTC
 - Metastatic foci may:
 - Not include cells with nuclear features of PTC
 - Be thyroglobulin negative or weakly positive

Fig. 28-66. Columnar cell variant.

Immunohistochemical staining in CCV includes thyroglobulin immunoreactivity that can vary from case to case and even within the same case, including (A) left, diffuse and intense thyroglobulin reactivity; right, areas completely thyroglobulin negative; (B) TTF-1 (nuclear) reactivity is typically diffuse and strong.

- TTF-1 staining should be used in conjunction with thyroglobulin to confirm thyroid gland origin
- Distant metastasis:
 - Include to lung and bone may occur
 - Usually occur in cases with extrathyroidal extension
- Associated with high mortality rates with death occurring within 4 years from diagnosis; however, prognosis not uniformly unfavorable but varies depending on presence or absence of extrathyroidal extension (ETE):
 - Large tumors with extrathyroidal extension:
 - Aggressive behavior with distant metastasis (e.g., lungs) and increased mortality rates over shorter follow-up periods

- Tumors confined to thyroid gland without extra-thyroidal invasion
 - Prognosis similar to conventional PTC even in presence of nodal metastatic disease

Hobnail Variant of PTC (HVPTC)

(Fig. 28-69)

Definition: Aggressive type of PTC characterized by cells with hobnail or micropapillary features:

- Should be present in at least 30% of a given tumor but even tumors with 10% hobnail (micropapillary) features may behave aggressively

Synonyms: Papillary carcinoma with prominent hobnail features; PTC with micropapillary features

Clinical

- Rare tumor type representing less than 1% of all PTCs
- More common in women than in men; occur over a wide age range from third to eighth decades of life but most common in the sixth decade
- Clinical presentation includes:
 - Neck mass associated with dyspnea owing to compression of trachea
 - Cervical lymphadenopathy
 - History of multinodular goiter

Pathology

Fine-Needle Aspiration Biopsy

- Highly cellular with bloody background and scant colloid
- Cells arranged in papillary-like clusters or micropapillary groups
- Cell population consists of medium-sized cells with “tear-drop” cytoplasm, apically placed nuclei, producing surface bulge resulting in hobnail appearance
- Nuclei may show variable degrees of atypia, occasional eosinophilic intranuclear pseudoinclusions, and grooves:
 - Nuclear stratification and mitotic figures, including atypical forms, may be present.

Gross

- Range in size from 1.0 cm to 5.0 cm
 - Mean 3.0 cm
 - Often include multiple nodules in one or both thyroid lobes
 - Less commonly may be a single encapsulated nodule with or without central degeneration and hemorrhage

Histology

- Findings include:

Fig. 28-67. Columnar cell variant.

The prognosis associated with the columnar cell variant correlates with the extent of invasion and not necessarily on the cell type. **A**, Tumors that are encapsulated without invasion (as shown here) or that are minimally invasive within the thyroid gland without extrathyroidal extension often have a favorable prognosis without metastasis and/or increased mortality. **B** and **C**, In contrast, this CCV with clear cytoplasmic change invaded perithyroidal soft tissues, approximating (but not extending into) skeletal muscle, and metastasized (**D**) to the lungs, showing similar clear cell change as the primary tumor and ultimately resulting in patient death.

- Papillary pattern without colloid characterized by variably sized complex papillary and micropapillary structures:
 - Papillae may contain prominent vascular cores covered by cuboidal or oval epithelium with:
 - Nuclei located in middle or in apex of cytoplasm with cellular discohesiveness and bulging of apical surface producing hobnail appearance
 - Increased nuclear-to-cytoplasmic ratio
 - Moderate to marked pleomorphism
 - Dense eosinophilic cytoplasm with well-defined borders
 - Cytomorphologic features of conventional PTC, including enlarged irregular-appearing and overlapping nuclei with clear chromatin, nuclear grooves, and pseudoinclusions may present in focal areas.
- Follicular pattern with limited amounts of colloid characterized by:
 - Variably sized follicles lined by neoplastic epithelium (two to four cells thick) with hobnail cytologic features similar to those in papillary pattern
- Clustered pattern characterized by clusters of cancer cells with hobnail nuclear features forming

Fig. 28-68. Columnar cell versus tall cell.

Columnar cell variant versus tall cell variant of papillary thyroid carcinoma (PTC). The histologic distinction between these two variants of PTC characterized by “tall” cells is stark, allowing for ready differentiation. **A**, Columnar cell variant is characterized by (tall) columnar cells with nuclear stratification. **B**, Tall cell variant is characterized by cells that are three times as long as wide with pale eosinophilic cytoplasm and distinct cell membranes.

papillary structures without colloid and fibrovascular cores

– May be associated with angiolymphatic spaces

- Increased mitotic activity and atypical mitoses commonly seen:
 - Mitotic rate of ≥ 3 mitoses per 10 high-power fields
- Necrosis not present
- Psammoma bodies can be seen but usually are not numerous.
- Extensively invasive, including:
 - Vascular invasion
 - Extrathyroidal extension

- Concomitant foci with tall cell features, poorly differentiated thyroid carcinoma, and undifferentiated (anaplastic) thyroid carcinoma reported
- Immunohistochemistry:
 - Lesional cells reactive for:
 - Thyroglobulin, TTF1-1 (nuclear)
 - HBME-1 and nuclear expression of p53
 - Membrane staining for β -catenin and E-cadherin:
 - Patchy lateral and or basolateral membrane positivity
 - MUC1 reactivity with characteristic “inside-out” staining pattern in micropapillary component
 - Increase proliferative index by Ki67 staining:
 - Ranges from 2% to 20% (mean 10%)
- Cytogenetics and molecular genetics:
 - *BRAF* V600E mutation in majority of cases (>50% and as high as 80%)
 - *RET/PTC1* rearrangement:
 - In some reported not identified
 - In other reported found in up to 20% of cases

Treatment and Prognosis

- Treatment includes total thyroidectomy and cervical lymph node dissection
- Aggressive tumor often associated with:
 - Lymph node metastasis (75%) at presentation:
 - Metastases show hobnail pattern of growth similar to primary tumor
 - Advanced clinical stage (AJCC Stage III or IV) at presentation
 - Extrathyroidal extension
 - Recurrent disease
 - Distant metastasis most commonly to lung > brain, bone, liver, spinal cord, soft tissues, pancreas, psoas muscle, epiglottis, larynx, nasopharynx, base of tongue, and tonsils:
 - Metastases show hobnail pattern of growth similar to primary tumor.
 - Increased mortality rates in most but not all cases

POORLY DIFFERENTIATED THYROID CARCINOMA (PDTTC) (Figs. 28-70 through 28-75)

Definition: Malignant epithelial thyroid neoplasm showing histologic and biologic features that are intermediate between differentiated thyroid carcinomas and anaplastic (undifferentiated) thyroid carcinoma.

- Turin proposal established criteria for diagnosis including:
 - Presence of solid, trabecular, insular pattern of growth

Fig. 28-69. Hobnail variant of PTC.

A, This variant of PTC is characterized by variably sized papillae with vascular cores covered by cuboidal or oval epithelial cells with surface bulge producing a hobnail appearance. **B**, Enlarged hyperchromatic nuclei with increased nuclear-to-cytoplasmic ratio and **(C)** intranuclear inclusions (*arrowhead*) are present. In addition, **(D)** psammoma bodies (*arrowhead*) and **(E)** squamous eddies may be identified.

Fig. 28-70. PDTC.

Poorly differentiated thyroid carcinoma (PDTC) characterized by insular, trabecular, and solid growth, confluent area of necrosis and invasive growth (i.e., angioinvasion into large size vascular space [*left side of illustration*]). Uncommonly, PDTC may be encapsulated and noninvasive (*not shown*), which is associated with significantly improved overall survival compared to invasive tumors.

- Absence of conventional nuclear features of papillary thyroid carcinoma
- Presence of at least one of following features:
 - Mitotic activity ≥ 3 per 10 high-power fields
 - Tumor necrosis
 - Convoluted nuclei
- Growth pattern alone including insular, solid, trabecular do not define a given thyroid tumor as poorly differentiated because such growth patterns can be seen in differentiated thyroid tumors.
- Thyroid carcinomas with high-grade features:
 - Represent PDTC defined on basis of mitosis and necrosis
 - May be present in tumors with features of papillary thyroid carcinoma and follicular thyroid carcinoma (non-oncocyctic and oncocyctic).
 - Criteria include:
 - ≥ 5 mitoses per 10 high-power fields
 - Tumor necrosis
- Amount of poorly differentiated foci for diagnosis of PDTC:
 - Minor poorly differentiated features in differentiated thyroid carcinomas shown to portend more aggressive features:
 - In some studies reported as $<20\%$
 - In other studies $\geq 10\%$ poorly differentiated foci shown to affect prognosis significantly

Synonym: “Insular” carcinoma

Clinical

- Uncommon tumor representing less than 2% of all thyroid cancers:
 - In mountain region of northern Italy represents 4% to 7% of all thyroid malignant neoplasms
- More common in women than in men; most common in the sixth decade of life:
 - Typically occurs a decade later than differentiated thyroid cancers
 - May occur in children but rather rare occurrence
- Presentation includes presence of thyroid mass of varying duration:
 - Some are of recent duration (within 1 year)
 - Others occur in long-standing enlarged thyroid (e.g., goitrous thyroid gland)
 - Rarely, patients present with distant metastasis.
- At presentation often (but not always) associated with locally advanced disease, including extrathyroidal extension
- Patients are euthyroid.
- Appear as “cold” nodules on thyroid scanning:
 - Owing to loss of avidity for radioiodine, tumor may not be detected on scanning but may require FDG-PET.
- Usually arise de novo but may be associated with (transform from) differentiated thyroid carcinomas, including papillary or follicular carcinoma
- Etiology:
 - Unknown

Pathology Fine-Needle Aspiration Biopsy

- Cellular aspirates composed of discohesive, small, monotonous, round to oval cells that may include a plasmacytoid appearance with eccentric hyperchromatic nuclei, smooth nuclear contours, small to inconspicuous nucleoli, and finely granular, ill-defined cytoplasm; occasional binucleate cells may be identified.
- Nuclear atypia and pleomorphism are usually mild.
- Microfollicles are variably seen and scant colloid is present.
- Necrosis and mitotic figures may or may not be identified.

Gross

- Typically overtly infiltrative with extrathyroidal extension but may be encapsulated (partly or completely)
- Vary in size from 1 to 10 cm but most measure >5 cm
- Solid, firm, and tan-white with associated hemorrhage and necrosis

Fig. 28-71. Poorly differentiated thyroid carcinoma.

Growth patterns in poorly differentiated thyroid carcinoma include **(A)** insular, **(B)** trabecular, **(C)** solid (lower) juxtaposed to areas with insular pattern (*upper*). **D**, Cribriform may uncommonly be identified.

Histology

- Growth patterns:
 - Dominant growth patterns include solid, trabecular, and insular:
 - Solid growth characterized by diffuse sheets of tumor that may be separated by variable amount of fibrovascular stroma
 - Trabecular pattern characterized by elongated cords or ribbons of tumor
 - Insular growth arranged in well-defined round to oval cell nests or islands (“insulae”) separated by varying amount of fibrovascular stroma
 - Retraction artifact characterized by clear areas surrounding tumor nests may be present.
 - Papillary architecture may be focally identified.
 - Microfollicles containing dense colloid may be identified but typically follicular pattern with abundant colloid formation not present:
 - Presence of readily identifiable colloid-filled follicles in PDTC represent residual foci of differentiated thyroid tumor, including follicular adenoma/carcinoma, papillary carcinoma
- Cytomorphology:
 - Monotonous population of small cells with round, hyperchromatic to vesicular nuclei with

Fig. 28-72. Poorly differentiated thyroid carcinoma.

Whether associated with **(A)** solid growth or **(B)** insular growth the cytomorphic findings in poorly differentiated thyroid carcinoma include a rather monotonous population of small cells with round, hyperchromatic to vesicular nuclei with smooth nuclear contours, inconspicuous to small nucleoli and indistinct cytoplasm. Some of the cells are small and hyperchromatic, with irregularities in the nuclear contour referred to as so-called convoluted nuclei. **C**, Rhabdoid cells may infrequently be identified in poorly differentiated thyroid carcinoma. Overall, there is an absence of nuclear features diagnostic for PTC.

Fig. 28-73. Poorly differentiated thyroid carcinoma.

The diagnostic criteria for poorly differentiated thyroid carcinoma require the presence of **(A)** increased mitotic activity (*arrows*) and **(B)** necrosis (*left*). Mitotic activity should be on the order of more than 3 to 5 mitoses per 10 high-power fields; necrosis is coagulative type involving groups of tumor cells.

Fig. 28-74. IHC in PDTC.

Immunohistochemical staining in poorly differentiated thyroid carcinoma includes **(A)** thyroglobulin and **(B)** TTF-1 (nuclear). Typically, thyroglobulin reactivity may be focal limited to abortive or small follicles containing colloid, limited to isolated cells as paranuclear globules or vacuoles or may be completely absent; TTF-1 staining tends to be strong and diffuse.

- smooth nuclear contours, inconspicuous to small nucleoli, and indistinct cytoplasm
- Cells with larger nuclei, vesicular nuclear chromatin, smooth nuclear contours, and identifiable nucleoli may be identified.
- Convoluted nuclei
 - Small, hyperchromatic, raisin-like nuclei
 - Some irregularities in nuclear contour
- Absence of nuclear features diagnostic for PTC
- Other cell types seen in PDTC include:
 - Oncocytic cells
 - Rhabdoid cells
- Mitotic activity:
 - Increased mitotic activity identified

Fig. 28-75. Follicular adenoma with insular growth.

Insular growth can be seen in a variety of thyroid lesions that are not poorly differentiated thyroid carcinoma. As such, the presence of insular growth is not in and of itself an indicator of malignancy. This thyroid neoplasm with insular growth is encapsulated without evidence of invasive growth, necrosis, and/or increase in mitotic activity representing a follicular adenoma with an insular growth pattern. Other thyroid lesions that may have an insular growth pattern (in part or dominant) include adenomatoid nodules, papillary thyroid carcinoma, follicular thyroid carcinoma, and medullary thyroid carcinoma (not shown).

- Turin criteria is ≥ 3 per 10 high-power fields
- ≥ 5 mitoses per 10 high-power fields proposed in criteria associated with thyroid carcinomas with high-grade features
 - Atypical mitoses may be found.
- Necrosis:
 - Commonly found
 - Represents coagulative-type necrosis involving groups of tumor cells and not individual cell necrosis
 - May be focal, appearing as small foci in center of solid nests or insulae
 - May be more extensive, appearing as confluent foci

- In this setting may spare areas around blood vessels, creating peritheliomatous appearance
- Invasiveness:
 - Most PDTCs are extensively invasive, including:
 - Intrathyroidal invasion with capsular invasion, vascular invasion, and invasion into adjacent thyroid parenchyma
 - Extrathyroidal extension
 - May be noninvasive (noninvasive PDTC or non-invasive thyroid carcinoma with high-grade features)
 - Encapsulated without evidence of invasion
 - Entire tumor should be submitted to exclude presence of invasion.
- Hobnail features:
 - Papillary thyroid carcinoma with hobnail features (>10%) reported in association with poorly differentiated thyroid carcinoma (22% of cases)
 - Suggest that hobnail features may be manifestation of higher-grade transformation
- Immunohistochemistry:
 - Thyroglobulin, TTF-1 (nuclear), and PAX8 (nuclear) positive:
 - Thyroglobulin reactivity may vary from case to case and even within same case showing:
 - Very focal limited to abortive or small follicles containing colloid
 - Limited to isolated cells as paranuclear globules or vacuoles
 - Completely negative
 - Typically not diffusely/strongly reactive
 - TTF-1 tends to be diffuse.
 - Cytokeratin reactivity including AE1/AE3, CAM 5.2, CK7
 - p53 reactivity (focal or diffuse)
 - Calcitonin, synaptophysin, and chromogranin negative
 - High proliferation indices as determined by Ki67 (MIB1) staining
 - Rhabdoid cells negative for thyroglobulin but are vimentin positive owing to presence of intermediate filaments.
- Cytogenetics and molecular genetics:
 - Limited utility owing to absence of specific mutations
 - β -catenin gene mutation (*CTTNB1*) may be identified.
 - Point mutations of *RAS* oncogene in significant proportion of cases
 - *BRAF* mutations uncommon unless arising in association with PTC
 - *RET/PTC* rearrangement uncommon
 - *PAX8/PPAR γ* rare
 - Telomerase reverse transcriptase (TERT) promoter mutations identified

- Associated with more aggressive behaving thyroid cancers, including (other than PDTC):
 - Tall cell variant of PTC
 - Undifferentiated (anaplastic) thyroid carcinoma
- *PIK3CA*, *PTEN*, and *CDKI* mutations present in 14% to 20% of PDTCs

Differential Diagnosis

- Medullary thyroid carcinoma (MTC):
 - Presence of immunoreactivity for calcitonin, synaptophysin, and chromogranin
 - Absence of immunoreactivity for thyroglobulin and PAX8
 - TTF-1 may be positive in MTC and PDTC.
- Undifferentiated (anaplastic) carcinoma (see below).
- Papillary thyroid carcinoma, solid variant:
 - Typical nuclear features of PTC
 - Absence of increased mitotic activity and necrosis
 - Presence of more diffuse thyroglobulin reactivity as might be seen in PDTC

Treatment and Prognosis

- Multimodality therapy including:
 - Total thyroidectomy
 - Neck dissection for patients with lymph node disease
 - Postoperative radioactive iodine:
 - Advocated for all patients with PDTC owing to high mortality rates
 - However, conflicting data in literature on avidity for radioactive iodine
 - Adjuvant external beam radiation advocated for patients with:
 - T3 tumors without distant metastases
 - T4 tumors
 - Unresectable or incompletely excised tumors
 - Locoregional recurrence
 - Regional lymph node metastases
- Recurrence and metastasis following treatment occur in a high proportion of cases (>60%)
- Lymph node and distant metastases occur in approximately 60% and 70% of cases, respectively.
- Death from disease is common:
 - Caused by uncontrolled local or distant metastatic disease
 - In contrast to rapid demise typically associated with undifferentiated (anaplastic) carcinoma, death from PDTC occurs after several years.
- Survival rates:
 - 5-year survival rate of 50% to 72%
 - 10-year survival rate of 46%
- Findings associated with worse outcome include:
 - Patients ≥ 45 years of age
 - Tumor measuring greater than 4 cm (decreased progression-free survival)

- Presence of extrathyroidal extension into perithyroidal soft tissues (correlates with decreased overall survival)
- Presence of metastasis
- RAS mutation
- Presence of insulin-like growth factor II messenger RNA protein-3 (IMP3) immunoreactivity
- Noninvasive (encapsulated) PDTC:
 - Significantly improved overall survival compared to invasive tumors
 - Indolent behavior even in presence of extensive tumor necrosis
 - Recent report of widely metastatic disease in noninvasive follicular carcinoma with high-grade features, including presence of focal necrosis (<5%) and 14 mitoses per 10 high-power fields.

UNDIFFERENTIATED (ANAPLASTIC) THYROID CARCINOMA (UTC) (Figs. 28-76 through 28-85)

Definition: Highly aggressive, undifferentiated thyroid malignant neoplasm with immunohistochemical and ultrastructural evidence of epithelial differentiation arising from follicular epithelial cells.

Synonyms: Sarcomatoid carcinoma; pleomorphic carcinoma; metaplastic carcinoma; spindle cell carcinoma; giant cell carcinoma

Clinical

- Uncommon thyroid malignant tumor representing less than 5% of thyroid malignancies.
- More common in women than in men; typically occur in older patients usually >seventh decade of life; rarely occurs in patients younger than 50 years of age
- Clinical presentation classically includes:
 - Rapidly enlarging neck or thyroid mass occurring over short periods of time (weeks to months):
 - Rapid thyroid enlargement most common in patients with long-standing goiter
 - Less often, rapid enlargement may be associated with a differentiated thyroid carcinoma (papillary or follicular carcinoma).
 - Often, neck enlargement associated with dyspnea, dysphagia, hoarseness, vocal cord paralysis
 - Locoregional and/or distant (e.g., lungs, bone, brain) metastases at presentation may be identified:
 - Unusually, metastatic disease may occur in absence of overt thyroid or neck mass.
- Tumors are large, bulky, firm to hard masses distorting appearance of neck and may cause reddening of the overlying skin.
 - Owing to presence of extrathyroidal extension at presentation, a rather common finding (up to 50% of patients), fixation present to adjacent structures, including:
 - Skin, trachea, larynx, esophagus, extrinsic skeletal muscles, and nerves (e.g., recurrent laryngeal nerves, others)
 - Invasion and/or occlusion of jugular vein or carotid artery may occur.
 - Cutaneous ulceration with necrosis may be seen and tumors may grow through skin.
 - Owing to tendency for these tumors to be very large, cervical adenopathy may be difficult to appreciate.
- Most patients are euthyroid, although both thyroid hypofunction and hyperfunction may uncommonly occur:
 - Thyroid hyperfunction due to destruction of thyroid follicular epithelium with release of colloid and thyroid hormone into circulation
 - May be associated with humoral hypercalcemia of malignancy due to parathyroid hormone-related protein secretion
- Radiology:
 - Hypofunctioning (“cold”) lesion on thyroid scanning
 - Uptake in either primary tumor or in metastatic foci may represent remnants of better differentiated component.
 - CT scan (preferred diagnostic modality):
 - Large infiltrative mass with irregular borders of low attenuation with cystic areas
 - Punctate calcifications and necrosis frequently present
 - Diffuse enlargement and replacement of thyroid gland by hypodense tumor may be identified.
 - Extensive spread outside thyroid gland with infiltration into soft tissue of neck as well as into adjacent structures (trachea, larynx, jugular vein, carotid artery, other) may be identified.
 - Nodal metastasis (cervical neck, mediastinal) may be identified.
 - Ultrasonography:
 - Hypoechoic
- Etiology:
 - Association with pre- or coexisting thyroid disease:
 - In majority of cases, develops in setting of pre-existing thyroid neoplasm, the majority of which are differentiated follicular-derived tumors, including:
 - Conventional papillary thyroid carcinoma and variants thereof:
 - Most common “precursor” neoplasm (>80% of cases showing differentiated and undifferentiated components)
 - Follicular carcinoma and variants thereof (e.g., oncocytic variant)

Fig. 28-76. Anaplastic thyroid cancer on contrast-enhanced CT.

A, Axial CT image at the level of the cricoid cartilage shows diffuse enlargement and replacement of the thyroid gland with hypodense tumor (*). There are necrotic bilateral cervical lymph node metastases (N). **B**, Axial CT scan inferior to **A** at the level of the trachea shows extensive involvement of the thyroid gland with anaplastic carcinoma. There is extensive spread outside the thyroid capsule into adjacent soft tissues of the neck anteriorly (white arrow), as well as laterally with invasion into the right jugular vein (black arrow), which is occluded. *Common carotid arteries; JV, patent left jugular vein. **C**, Axial CT image shows multiple bilateral necrotic metastatic lymph nodes (N) in the midcervical lymph chains. **D**, Axial CT scan of the chest shows mediastinal lymph node metastasis (N). (From Som and Curtin: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Figure 41-77, p 2646.)

- Follicular adenoma
- Less often, may develop from pre-existing poorly differentiated thyroid carcinoma
 - May develop from pre- or coexisting adenomatoid nodule(s) in patients with history of longstanding (decades-long) goitrous thyroid
 - In spite of development in setting of antecedent thyroid disease, probability of anaplastic transformation of a pre-existing follicular lesion is considered low.
- Iodine deficiency:
 - Higher incidence in areas of dietary iodine deficiency and endemic goiter
- Includes alpine regions
- Reduction in incidence with iodine supplementation
 - Radiation exposure (external and radioactive iodine)
 - Implicated as potential causative factor
 - Approximately 10% have history of radiation exposure, and 10% to 12% have history of another malignant neoplasm.
 - Probability of anaplastic transformation occurring is so low that it should not play any role in considering whether to use radiation in treatment.

Fig. 28-77. Undifferentiated (anaplastic) thyroid carcinoma, fine-needle aspiration biopsy (FNAB).

Thyroid-related neck mass showing (A) cellular smear characterized by markedly pleomorphic cells with highly atypical hyperchromatic nuclei and associated necrosis and inflammation (Papanicolaou stain). B, Round to oval, spindle-shaped, and multinucleated highly malignant cells (Diff-Quik stain). Immunohistochemical staining on a cell block (not illustrated) showed the lesional cells to be reactive for cytokeratins and PAX8 but negative for thyroglobulin and TTF-1. The FNAB diagnosis would be “malignant; poorly differentiated carcinoma consistent with undifferentiated (anaplastic) thyroid carcinoma (Bethesda VI).”

Pathology

Fine-Needle Aspiration Biopsy

- Cellular aspirates with sheets, cell clusters, or isolated cells
- Large pleomorphic cells with bizarre hyperchromatic nuclei, prominent single or multiple nucleoli, and abundant cytoplasm
- Spindle-shaped cells are commonly seen.
- Mitoses and necrotic background are present.

Fig. 28-78. UTC.

Undifferentiated (anaplastic) thyroid carcinoma appearing as tan-white tumor with foci of necrosis replacing most of the thyroid gland. The tumor is grossly invading outside the confines of the thyroid gland (left).

Gross

- Large and widely invasive tumors that vary in appearance:
 - Often tan-white and firm to hard but may appear as mottled soft to rubbery due to extensive hemorrhage and necrosis
 - Rarely, anaplastic foci may appear as small firm to hard solid areas in a nodule or differentiated neoplasm.
 - Remnant of non-neoplastic thyroid gland may be limited in extent or absent due to replacement by anaplastic carcinoma.
- Range in size from 1 to 20 cm:
 - Usually measure >5 cm
 - Mean size 6.4 cm
- Extrathyroidal invasion commonly present

Histology

- Wide variation in histologic findings between tumors and even within same tumor
- Growth patterns include solid, fascicular, and storiform:
 - Admixtures of different growth patterns can be seen in any one case.
- Cytologically, irrespective of cell type (see below) features common to all tumors include presence of:
 - Marked nuclear pleomorphism
 - Increased mitotic activity with atypical mitoses
 - Extensive coagulative tumor necrosis
 - Extensive invasive growth, including:
 - Within thyroid parenchyma, into adjacent (extrathyroidal) tissues including skeletal muscle, adipose tissue
 - Vascular invasion, neurotropism

Fig. 28-79. UTC.

Undifferentiated (anaplastic) thyroid carcinoma characterized by fascicular growth and cells with high-grade nuclear features associated with remnants of **(A)** papillary thyroid carcinoma and **(B)** differentiated follicular neoplasm.

- Absence of follicular differentiation (in undifferentiated component)
- Among the cell types the most common are spindle-shaped, giant cell, and squamoid:
 - Spindle-shaped (sarcoma-like):
 - Most common
 - Composed of elongated and/or pleomorphic and hyperchromatic nuclei
 - Storiform and fascicular (long fascicles) growth
 - Heterologous elements may be present, including malignant bone and cartilage.
 - May include staghorn (hemangiopericytoma-like) vascularity
 - Giant cells:
 - Pleomorphic, round to oval cells characterized by bizarre-appearing nuclei
 - Often multinucleated with abundant eosinophilic to granular-appearing cytoplasm
 - Intracytoplasmic hyaline globules may be identified.
 - May represent only neoplastic cellular component or may be admixed with spindle-shaped (sarcomatous) foci
 - Pseudoglandular and pseudoangiomatous foci may be present.
- Squamoid (epithelioid):
 - Least common
 - Retention of epithelial appearance in form of nested or cohesive growth pattern suggestive of an epithelial neoplasm
 - Predominantly nonkeratinizing
 - Squamous differentiation including keratinization (keratin pearls, individual cells) may be present but usually does not make up majority of tumor.
 - Squamoid cell foci generally are devoid of giant cells but may be admixed with spindle-shaped (sarcomatous) foci.
- Histologic variants are rare and include:
 - Paucicellular variant:
 - Gross appearance may simulate features of Riedel disease, including homogenous, firm, tan-white
 - Characterized by relatively hypocellular proliferation with prominent associated fibrosis and hyalinization
 - Scattered lesional cells, often spindle-shaped, embedded in fibrous stroma show cytomorphic features of malignancy, including marked nuclear atypia with increased mitotic activity, necrosis, and vascular invasion:
 - Vascular invasion assists in differentiating the paucicellular variant from Riedel disease.
 - Lesional cells typically are cytokeratin positive.
 - Rhabdoid cell type (rhabdoid tumor of thyroid gland):
 - Thyroid tumors predominantly (approximately 30% to 40% of total tumor content) composed of rhabdoid cells
 - Controversial cell type infrequently seen in thyroid tumors with a limited number of cases reported in the world literature
 - Predominantly occurs in women (6:1); occur over a wide age range from the fifth to seventh decades of life (mean age, 55 years)
 - Occurs in association with differentiated thyroid carcinoma (i.e., follicular carcinoma or thyroid papillary carcinoma)
 - Some authorities categorize rhabdoid tumors of thyroid within category of undifferentiated

Fig. 28-80. Undifferentiated (anaplastic) thyroid carcinoma.

Undifferentiated (anaplastic) thyroid carcinoma. Growth patterns include **(A)** solid and **(B)** fascicular to storiform (sarcoma-like). Lesional cells include **(C)** spindle-shaped; **(D)** pleomorphic; **(E)** giant cells; **(F)** squamoid. Irrespective of the cell type, there is marked nuclear pleomorphism and increased mitotic activity with absence of cellular differentiation.

Fig. 28-81. Undifferentiated (anaplastic) thyroid carcinoma.

Immunohistochemical staining in undifferentiated (anaplastic) thyroid carcinoma typically includes an absence of thyroglobulin and TTF-1. **A**, Cytokeratins are typically patchy with scattered positive cells although in any given case may be diffuse and strong (AE1/AE3). PAX8 (nuclear) staining represents the most useful thyroid follicular epithelial cell marker in the diagnosis and is present in the majority of cases reactive in **(B)** spindle-shaped and **(C)** pleomorphic cells.

- (anaplastic) carcinomas, whereas other authorities classify it within category of poorly differentiated carcinoma (see later)
- Invasive, solid, and highly cellular composed of rhabdoid cells characterized by:
 - Presence of large cells with abundant eosinophilic to amphophilic cytoplasm, eosinophilic cytoplasmic inclusions, eccentric nuclei with prominent eosinophilic nucleoli
 - Increased mitotic figures and necrosis are present.
- Rhabdoid cells are:
 - Immunoreactive for cytokeratins, PAX8, vimentin, sarcomeric actin, and myoglobin
 - Tend to be nonreactive for thyroglobulin, TTF-1, desmin, smooth muscle actin, and S100 protein
- One case of rhabdoid tumor of the thyroid reported to have *RET/TPC3* rearrangement, a finding that:
 - Confirms an underlying papillary thyroid carcinoma
 - Indicates a direct relationship of rhabdoid tumor to the differentiated carcinoma.
- Lymphoepithelioma-like:
 - Unusual variant resembling undifferentiated-type carcinoma of other sites (lung, nasopharynx)
 - Composed of sheets or islands of cells with large round to oval nuclei with vesicular chromatin and prominent eosinophilic nucleoli
 - Associated lymphoplasmacytic infiltrate may be present.
 - Absence of Epstein-Barr virus

Fig. 28-82. Rhabdoid cells.

Rhabdoid cell type is characterized by **(A)** presence of large cells with abundant eosinophilic cytoplasm, eosinophilic cytoplasmic inclusions, and eccentric nuclei. Rhabdoid cells are immunoreactive for **(B)** cytokeratins (CAM 5.2) and **(C)** PAX8 (nuclear).

Fig. 28-83. Histologic variants of UTC.

Other findings that can be seen in undifferentiated (anaplastic) thyroid carcinoma include **(A)** paucicellular, **(B)** osteoclastic giant cells, and **(C)** heterologous bone.

Fig. 28-84. Metastatic UTC.

In undifferentiated (anaplastic) thyroid carcinoma metastatic disease often occurs early in the disease course including **(A)** to regional lymph nodes with tumor in the subcapsular sinus (*arrow*) and in node parenchyma; **(B)** lesional cells are strongly and diffusely PAX8 reactive (nuclear), including cells in subcapsular sinus (*arrow*).

- Absence of CD5 reactivity would differentiate this tumor type from carcinoma showing thymus-like element (CASTLE)
- Angiomatoid:
 - Presence of anastomosing tumor cell-lined clefts that may contain blood simulating histology of angiosarcoma
- Small cell type:
 - Has been considered a type of undifferentiated carcinoma
 - Existence of a true small cell type of carcinoma in the thyroid is questionable.
 - These tumors more likely represent lymphoma, a variant of medullary carcinoma, a variant of

Fig. 28-85. Noninvasive UTC.

In rare examples, undifferentiated (anaplastic) thyroid carcinoma may be encapsulated without invasion both by **(A)** macroscopic and **(B)** microscopic evaluation. The absence of invasion is uncommon, requiring submission of the entire tumor to exclude invasive growth. Patients with noninvasive undifferentiated (anaplastic) thyroid carcinoma may experience longer survival periods as compared to the rapid demise typically associated with the majority of patients whose cancers are invasive.

- follicular carcinoma (e.g., insular carcinoma), metastatic small cell carcinoma.
- Hobnail features:
 - Presence of foci with hobnail features reported in 1 of 26 anaplastic carcinomas (3.8%) (more frequently in poorly differentiated thyroid carcinoma)
 - Findings suggest that hobnail features may be manifestation of higher-grade transformation.
- Osteoclastic-type giant cells:
 - Characterized by numerous nuclei with limited atypical cytologic features that may be present in a small percentage of cases

- Typically osteoclastic-type giant cells are seen in or near hemorrhagic areas.
- Nature of osteoclastic giant cells remains uncertain but likely represent reactive cells of macrophage/histiocyte origin rather than neoplastic cells as evidenced by their ability to phagocytize inflammatory cells, immunoreactivity with CD68 (KP-1), ultrastructural features, and presence of high levels of acid phosphatase activity.
- As noted previously:
 - In any given tumor mixed growth patterns and mixed cell types can be seen.
 - Irrespective of cell type, neoplastic cellular infiltrate:
 - Is undifferentiated without evidence of colloid formation
 - Is markedly pleomorphic with an increase in nuclear to cytoplasmic ratio; prominent eosinophilic nucleoli may be present
 - Has high mitotic rate with numerous atypical forms
 - Has associated foci of confluent necrosis and individual cell necrosis
- Stroma may have myxoid change or may have prominent collagen deposition.
 - An associated inflammatory cell infiltrate including many neutrophils may be present.
- Prominent vascularity is present, which may have a pericytic (“staghorn”) growth or resemble appearance of an angiosarcoma (interconnecting vascular channels lined by neoplastic cells)
- Heterologous elements, including bone and cartilage, may be present.
 - When present, these elements are usually seen in association with sarcomatous foci but can also be seen admixed with epithelial and giant cell infiltrates.
- Invasiveness:
 - Most UTCs are extensive invasion, including:
 - Intrathyroidal invasion of thyroid parenchyma, vascular invasion, peri- and intraneural invasion
 - Vascular space invasion (veins, arteries, and lymphatics) with replacement of endothelial cells and the development of tumor thrombi is often present.
 - Extrathyroidal infiltration including:
 - Perithyroidal soft tissues (muscle, vessels, nerves), invasion into larynx, trachea, and esophagus
 - May be noninvasive (noninvasive undifferentiated thyroid carcinoma)
 - Encapsulated without evidence of invasion
 - Entire tumor should be submitted to exclude presence of invasion.
- Differentiated thyroid lesion/neoplasm:
 - Remnants of a pre- or coexisting differentiated thyroid follicular-derived lesion may or may not be present.
 - Differentiated thyroid lesion includes:
 - Papillary thyroid carcinoma
 - Most common
 - May include follicular or tall cell variants
 - Less commonly may include:
 - Adenomatoid nodule
 - Follicular neoplasm (carcinoma, adenoma)
 - Poorly differentiated thyroid carcinoma
 - Presence of identifying differentiated thyroid lesion/neoplasm may be function of sampling
- Immunohistochemistry:
 - Undifferentiated component:
 - Reactivity with cytokeratins is most useful marker:
 - Identified in majority of cases
 - May vary but most often focally identified in scattered lesional cells
 - Should include array of cytokeratins including AE1/AE3, CAM 5.2, OSCAR
 - Epithelial membrane antigen (EMA):
 - Usually positive but with variable reactivity
 - Carcinoembryonic antigen (CEA) reactivity
 - Usually is limited to focal areas and/or scattered cells (epithelial, spindle-shaped, giant cells, paucicellular cells)
 - p63 (nuclear) reactivity:
 - Positive in majority of cases
 - Based on limited number of reported cases
 - PAX8 (nuclear) reactivity:
 - Most useful among thyroid follicular epithelial cell markers
 - Reported positive in up to 79% of cases
 - Thyroglobulin and TTF-1 (nuclear) reactivity:
 - Extremely variable and usually absent
 - Generally not helpful in diagnosis
 - Reactivity due to diffusion of thyroglobulin from destroyed non-neoplastic cells or thyroglobulin expression in entrapped differentiated tumor or non-neoplastic thyroid parenchyma can be seen and should not be interpreted as expression in undifferentiated component
 - Vimentin reactivity is usually present in all cellular components but is most reactive with spindle-shaped cells.
 - High proliferation indices as determined by Ki67 (MIB1) staining
 - Calcitonin, synaptophysin, and chromogranin negative
 - Evidence of epithelial-to-mesenchymal transition markers reported, including decreased expression of E-cadherin and increased

expression of Zinc Finger E-Box Binding Homeobox 1 (ZEB1):

- Epithelial mesenchymal transition (EMT) is major pathologic mechanism in tumor progression and is linked to acquisition of stem-like properties of cancer cells
- Electron microscopy:
 - Evidence of epithelial (follicular cell) differentiation, including specialized cell junctions (desmosomes) or microvilli may be present (approximately 50% of cases), but due to the poorly differentiated nature of these tumors evidence of epithelial differentiation may not be identified.
- Cytogenetics and molecular genetics:
 - Mutations of p53 gene found in high percentage of cases
 - A significant percentage of anaplastic carcinomas harbor *BRAF* mutations:
 - Consistent sharing of the same *BRAF* profile is present in cases in which thyroid papillary carcinoma and UTC occur together; this finding supports the notion that UTCs represent progressive malignant degeneration of a pre-existing, well-differentiated thyroid carcinoma
 - Given the high frequency of *BRAF* mutations in UTC, anti-*BRAF* therapy may offer potential benefits for these patients.
 - β -catenin gene mutation (*CTTNB1*) common occurrence
 - *RAS* and *BRAF* mutations may be present in approximately a third of cases.
 - Low prevalence of *RET/PTC* rearrangement and *PAX8/PPAR γ* fusion
 - Telomerase reverse transcriptase (TERT) promoter mutations identified
 - Associated with more aggressive behaving thyroid cancers, including (other than UTC):
 - Tall cell variant of PTC
 - Poorly differentiated thyroid carcinoma
 - *PIK3CA* and *PTEN* mutations may be present

Differential Diagnosis

- Poorly differentiated thyroid carcinoma
- Papillary thyroid carcinoma with:
 - Squamous metaplasia
 - Spindle cell metaplasia
 - Nodular fasciitis-like stroma
- Depending on the histologic variant, additional differential diagnoses may include:
 - Carcinoma showing thymus-like elements (CASTLE) for lymphoepithelial-like variant
 - Riedel disease for paucicellular variant
- Malignant lymphoma, diffuse, predominantly large cell type
- Malignant melanoma
- Angiosarcoma

- Other sarcomas (primary and secondary involvement from a neck soft tissue tumor), including:
 - Undifferentiated pleomorphic sarcoma
 - Malignant peripheral nerve sheath tumor
 - Leiomyosarcoma
- Medullary thyroid carcinoma
- Invasive carcinoma from non-thyroid origin (e.g., larynx, other)
- Parathyroid carcinoma

Treatment and Prognosis

- Multimodality therapy, including surgery, radiation, and chemotherapy
 - If possible, complete surgical excision is indicated.
 - Unfortunately, these tumors tend to be so large and extensively invasive at presentation that complete surgical excision is not possible, and debulking of tumor is all that can be done.
 - Postoperative external irradiation and chemotherapy administered but efficacy in treatment is questionable, at best
- Radioactive iodine therapy has no role in the management because undifferentiated thyroid carcinoma is not iodine avid.
- Combined surgical, external irradiation, and chemotherapy offer best chances of survival but, even with multimodality therapy, most patients die (owing to local relapse), with mortality rates of more than 95%:
 - Death often occurs within short periods of time (6 months).
 - Approximately 20% of patients survive for 1 year.
 - 5-year survival rate is <14% with median survival rates of 2.5 to 6 months.
 - Longer-term survival may occur in association with:
 - Patients under 60 years of age
 - Tumors with limited anaplastic foci in a predominantly differentiated neoplasm
 - Noninvasive tumors, tumors confined to thyroid (intrathyroidal), and/or tumors with limited invasive growth
 - Tumors less than 4 cm
 - Tumors amenable to complete surgical resection
- Metastatic disease occurs early (at presentation or soon thereafter):
 - Lymphatic (regional and distant) and hematogenous spread occur
 - Common metastatic sites include adrenal glands, lung, and gastrointestinal tract.
 - Histology of metastatic tumor resembles that of primary neoplasm, and all of the cellular components of primary tumor may appear in the

metastatic foci (except for the heterologous elements such as bone and cartilage).

- Targeted molecular therapy emerging as potentially promising in treatment and includes:
 - Tyrosinase inhibitors
 - Thailandepsin A (TDP-A), a histone deacetylase (HDAC) inhibitor
 - Mitotic kinases, including Polo-like kinase-1 (PLK1)
 - Combretastatin

UNUSUAL EPITHELIAL TUMORS OF THE THYROID GLAND

Primary Thyroid Mucoepidermoid Carcinoma

- Two entities included under designation of thyroid mucoepidermoid carcinoma, including:
 - Mucoepidermoid carcinoma
 - Sclerosing mucoepidermoid carcinoma with eosinophilia
- Literature appears to support separating these two tumor types as distinct entities based on apparent differences in light microscopic and immunohistochemical findings, although this issue has not been entirely resolved.
- Separation may be academic because both tumor types have a similar indolent biologic course.

Thyroid Mucoepidermoid Carcinoma (TMEC)

(Figs. 28-86 and 28-87)

Definition: Low-grade malignant thyroid tumor with histologic appearance similar to its low-grade salivary gland counterpart, including presence of epidermoid cells and mucous cells.

Clinical

- Rare thyroid malignant tumor
- More common in women more than in men; occurs over a wide age range (second through eighth decades), with most patients in the fifth through seventh decades of life
- Most common presenting complaint includes painless neck mass:
 - Less commonly, pain, hoarseness, and vocal cord paralysis may occur.
 - Extrathyroidal extension in approximately 20%:
 - Symptoms of tracheal, esophageal, and recurrent laryngeal nerve compression may be present.
- Patients are euthyroid.
- May occur in any portion of thyroid gland, including isthmus

Fig. 28-86. Thyroid mucoepidermoid carcinoma.

Thyroid mucoepidermoid carcinoma appearing as a circumscribed solid mass (upper) separated from adjacent thyroid gland.

- Radiology:
 - Hypoactive “cold” nodule on thyroid imaging
- Etiology:
 - No known etiologic factors
 - History of radiation exposure during childhood reported in limited cases
- Histogenesis:
 - Several theories for origin of TMEC, including:
 - Likely origin from squamous metaplasia of follicular epithelial cells (possibly as a metaplastic variant of papillary carcinoma); in support of this consideration includes:
 - Transitions from follicular epithelium or foci of papillary thyroid carcinoma
 - Occurrence in background of chronic lymphocytic (Hashimoto) thyroiditis:
 - ◻ Common setting in which to find squamous metaplasia including presence of keratinization and intercellular bridges
 - Presence of thyroglobulin, TTF-1, and PAX8 reactivity
 - Presence of psammoma bodies
 - Association with papillary thyroid carcinoma
 - Indolent biology
 - Tendency to metastasize to regional lymph nodes
 - Origin from ultimobranchial bodies or solid cell nests, but most associated findings (see immediately above) weigh against such origin
 - Origin from thyroglossal duct

Pathology

Fine-Needle Aspiration Biopsy

- Smears show epidermoid cells and mucus-secreting cells.
- Cellular sheets with a microcystic-like pattern containing hyaline bodies may be identified.

Fig. 28-87. Thyroid mucoepidermoid carcinoma.

A, Nodular proliferation that is delineated but unencapsulated composed of solid and cystic foci with associated fibrosis; chronic lymphocytic (Hashimoto) thyroiditis is seen in the adjacent non-neoplastic thyroid tissue (*upper left*). **B**, Squamous or epidermoid component may include horny pearl formation, as well as individual cell keratinization; a cluster of mucocytes (*left of center*) is seen intimately admixed with the squamous/epidermoid component. **C**, Cystic lesion including epidermoid cells and scattered mucocytes (*arrow*); note columnar-appearing cells with prominent cilia (*arrowheads*). **D**, Solid lesion composed of an admixture of squamous/epidermoid cells and scattered mucocytes. **E**, Mucicarmine staining shows the presence of intracytoplasmic and intraluminal mucin-positive (red) material.

Gross

- Solitary mass measuring up to 10 cm in greatest dimension
- Cut section shows solid, nodular-appearing tissue varying from tan-brown to yellow-orange and with a rubbery to firm consistency.
 - Cystic change can be seen.

Histology

- Circumscribed but unencapsulated predominantly solid mass:
 - Prominent cystic foci may be present.
- Neoplastic proliferation includes epidermoid cells admixed with mucocytes.
 - Epidermoid cells
 - Round to oval cells with round nuclei, prominent centrally located nucleoli, and eosinophilic cytoplasm
 - Horny pearl formation, individual cell keratinization, and intercellular bridges are seen.
 - Mild nuclear pleomorphism, slight increase in the nuclear to cytoplasmic ratio, and scattered mitotic figures can be seen.
 - Mucous cells
 - Cells with abundant clear to foamy-appearing cytoplasm and peripherally located hyperchromatic nuclei
 - Mucocytes are intimately admixed with epidermoid cells.
 - Extravasated mucinous material/pools may be present.
 - Psammoma bodies may be identified.
 - Columnar-appearing cells with prominent cilia resembling respiratory-type epithelium can be identified.
 - A mixed inflammatory cell infiltrate including mature lymphocytes and plasma cells can be seen within the neoplastic proliferation; eosinophils may predominate in any given tumor.
 - Intratumoral sclerosis composed of thick, acellular hyalinized bands of tissue can be seen and is not necessarily limited to those cases with abundant eosinophils (see below).
 - Chronic lymphocytic (Hashimoto) thyroiditis is commonly present in the surrounding non-neoplastic thyroid gland and may include foci of squamous metaplasia.
 - Associated lesions:
 - Papillary thyroid carcinoma (separate or admixed) including tall cell variant:
 - Undifferentiated (anaplastic) carcinoma reported in association with PTC
 - Follicular carcinoma, conventional, and oncocytic variant
 - Adenomatoid nodules may be seen.

- Generally confined to thyroid gland but extrathyroidal extension may occur.
- Histochemistry:
 - Mucocytes:
 - Presence of intracytoplasmic and intraluminal mucicarmine and diastase-resistant, PAS-positive material
 - Cystic spaces may also show mucicarminophilic material.
- Immunohistochemistry:
 - Cytokeratins positive including:
 - Low and high molecular weight
 - CK5/6
 - p63 reactivity may be present
 - Thyroglobulin, TTF-1, and PAX8 (nuclear):
 - Thyroglobulin staining may be focal or even absent.
 - Polyclonal carcinoembryonic antigen may be present in association with mucocytes.
 - Calcitonin, chromogranin, synaptophysin
- Cytogenetics and molecular genetics:
 - Marked abnormalities of the cadherin/catenin complex, including consistent neoexpression of P-cadherin and major alterations in the expression of E-cadherin
 - *CRTC1/MAML2* fusion transcript reported

Differential Diagnosis

- Metastatic mucoepidermoid carcinoma of salivary gland origin
- Primary thyroid squamous cell carcinoma
- Papillary carcinoma with squamous metaplasia
- Adenosquamous carcinoma: primary thyroid origin or (direct) invasion from a minor salivary gland mucoepidermoid carcinoma from the larynx or trachea
- Lymphocytic thyroiditis with epithelial-lined cysts
- Medullary carcinoma with squamous differentiation
- Branchial cleft-derived cysts

Treatment and Prognosis

- Surgery is preferred treatment:
 - May include lobectomy/subtotal thyroidectomy or total thyroidectomy
- Indolent tumor with excellent prognosis:
 - Rare cases associated with PTC with anaplastic transformation follow dire disease course associated with undifferentiated (anaplastic) carcinoma.
- Metastatic tumor:
 - Regional cervical lymph nodes metastasis common
 - Distant metastasis is uncommon but may occur (lung).
- Presence of extrathyroidal extension and metastatic disease considered adverse biologic factors in other

follicular epithelial-derived tumors, does not appear to adversely affect prognosis in TMEC

Sclerosing Mucoepidermoid Carcinoma with Eosinophilia (SMECE) (Fig. 28-88)

Definition: Low-grade malignant thyroid tumor with histologic appearance similar to its low-grade salivary gland counterpart, including epidermoid cells and mucous cell differentiation plus presence of prominent sclerotic stroma and eosinophil-rich inflammatory cell component.

- Considered distinct from thyroid mucoepidermoid carcinoma

Clinical

- Uncommon thyroid malignant tumor
- Demographics similar to mucoepidermoid carcinoma:
 - Affects women more than men
 - Occurs over a wide age range (second to eighth decades), with most patients in the fifth through seventh decades of life
- Most common presenting complaint that of painless neck mass:
 - Rarely associated with hoarseness, vocal cord paralysis
- Arises in thyroid glands affected by chronic lymphocytic (Hashimoto) thyroiditis, in particular, fibrous variant

Fig. 28-88. Sclerosing mucoepidermoid carcinoma with eosinophilia.

A, At low magnification the tumor (*left*) appears unencapsulated with associated sclerosis (*left*) and infiltrates into the adjacent thyroid gland (*center*), which is characterized by the presence of chronic lymphocytic (Hashimoto) thyroiditis. **B and C,** Infiltrating cohesive cords of tumor with associated sclerosis and numerous eosinophils. The epidermoid/squamous cell component includes (**B**) foci with prominent squamous differentiation to (**C**) more subtle squamous differentiation in the form of individual cell keratinization (*arrowheads*). **D,** Admixture of squamous/epidermoid cells and scattered mucocytes (*arrow*) with associated eosinophilic cell infiltrate (*left*).

- Patients are euthyroid
- May occur in any portion of thyroid gland, including isthmus
- Radiology:
 - Hypoactive “cold” nodule on thyroid imaging
- Etiology:
 - No known etiologic factors
- Histogenesis:
 - Presumed to arise from metaplastic squamous epithelium

Pathology Fine-Needle Aspiration Biopsy

- Clusters of epidermoid or glandular cells in background of inflammatory cells, including eosinophils:
 - Mucinous material/debris may be present.

Gross

- Lesion with ill-defined borders, although may be circumscribed
- Measure from approximately 1.0 cm to 13 cm
- Cut section shows solid, firm lesion with white to yellow color.
 - Cystic change can be seen.

Histology

- Circumscribed but unencapsulated to infiltrative lesion:
 - Most are infiltrative including extrathyroidal extension
- Neoplastic proliferation includes:
 - Presence of anastomosing cords and narrow strands of tumor cells infiltrating sclerotic stroma with associated mixed inflammatory cell infiltrate that includes prominent eosinophilic cell component as well as lymphocytes and mature plasma cells
 - Neoplastic cells show squamous or epidermoid differentiation, including keratinization, as well as occasional mucocytes and/or mucin pools
 - Clear cells may be seen typically representing a minor component (10% to 30%) of tumor:
 - Clear cells appear to be glycogen-rich squamous cells.
 - Mucous pools may be present but are uncommon.
 - Pseudoangiomatous appearance may be identified owing to loss of cohesion of tumor cells.
- Chronic lymphocytic (Hashimoto) thyroiditis commonly present in surrounding non-neoplastic thyroid gland and may include foci of squamous metaplasia.
- Perineural invasion and vascular invasion common
- Rarely associated with conventional papillary thyroid carcinoma
- Histochemistry:

- Mucocytes:
 - Presence of intracytoplasmic and intraluminal mucicarmine and diastase-resistant, PAS-positive material
 - Cystic spaces may also show mucicarmino-philic material.
- Immunohistochemistry:
 - Cytokeratin and TTF-1 (nuclear) positive
 - p63 positive in squamous/epidermoid cells
 - Polyclonal carcinoembryonic antigen may be present in association with mucocytes.
 - Thyroglobulin negative
 - Calcitonin, chromogranin negative

Differential Diagnosis

- Metastatic mucoepidermoid carcinoma of salivary gland origin
- Primary thyroid squamous cell carcinoma
- Papillary carcinoma with squamous metaplasia
- Adenosquamous carcinoma: primary thyroid origin or (direct) invasion from a minor salivary gland mucoepidermoid carcinoma from the larynx or trachea
- Chronic lymphocytic (Hashimoto) thyroiditis with cyst formation and prominent eosinophilic infiltrate
- Medullary carcinoma with squamous differentiation
- Branchial cleft-derived cysts

Treatment and Prognosis

- Total thyroidectomy is preferred treatment.
- Indolent tumor with excellent prognosis
- Metastatic tumor:
 - Occurs to cervical lymph nodes in approximately one third of patients at presentation
 - Distant metastasis is uncommon but may occur to lung and bone.
- Extrathyroidal extension:
 - Occurs in approximately 50% of patients
- Presence of extrathyroidal extension and metastatic disease considered adverse biologic factors in other follicular epithelial-derived tumors, does not appear to adversely affect prognosis

OTHER SQUAMOUS CELL MALIGNANT TUMORS OF THE THYROID GLAND

Squamous Cell Carcinoma (SCC)

(Figs. 28-89 through 28-91)

- Extraordinarily rare primary thyroid follicular cell-derived tumor entirely composed of cells with squamous differentiation

Fig. 28-89. Thyroid squamous cell carcinoma.

Primary squamous cell carcinoma of the thyroid may arise in association with (*left*) an adenomatoid nodule (*top*) with invasive growth composed of (*right*) squamous cells with nuclear pleomorphism and mitotic figures.

- Tend to arise in setting of long-standing thyroid disease, including goitrous thyroid and chronic lymphocytic (Hashimoto) thyroiditis:
 - Probably take origin from squamous metaplastic foci of follicular epithelial cells
 - Some classify within spectrum of undifferentiated (anaplastic) carcinoma.
- More common in women than men; wide age range from 20 to 90 years with mean age at diagnosis of 63 years
- Most common complaint is anterior neck mass that may be rapidly enlarging
 - Dyspnea or dysphagia may be present
 - Extension to adjacent structure found in majority of cases
- Spectrum of histologic changes includes well-, moderately, and poorly differentiated squamous cell carcinoma:
 - May be nonkeratinizing with features similar to nonkeratinizing carcinomas of the oropharynx and nasopharynx
 - In contrast to squamous metaplasia, squamous cell carcinomas show pleomorphism, increased nuclear to cytoplasmic ratio, hyperchromatic nuclei, increased mitotic activity, and invasive growth.
- Dense sclerotic stroma is present.
- Immunohistochemical staining includes:
 - Strong reactivity for cytokeratins (AE1/AE3 and CK19) and p63
 - Focal positivity for CK7 and CK18
 - Thyroglobulin and TTF-1 (nuclear) staining reactivity reported
- Negative staining, calcitonin, chromogranin, and synaptophysin
- Overexpression of p53
- High proliferative index as determined by Ki67 (MIB1)
- A spindle cell variant may occur either de novo or in relationship to papillary carcinoma variants (e.g., tall cell):
 - Occurs in older patients
 - Tumors are large, solid
 - Histology is similar to that of spindle cell squamous carcinoma of the upper aerodigestive tract, including differentiated squamous cell carcinoma and an associated pleomorphic spindle cell proliferation with increased mitotic figures, necrosis, and hemorrhage.
 - Extrathyroidal invasion is common.
 - Spindle and squamous cells are cytokeratin positive and thyroglobulin negative.
- Classification of these squamous cell tumors have been considered within the category of undifferentiated (anaplastic) thyroid carcinoma:
 - Histology of these tumors is readily recognizable as to merit its own classification separate from undifferentiated (anaplastic) carcinoma.
- Irrespective of into which category this tumor is placed, it behaves as a high-grade tumor akin to the behavior of anaplastic (undifferentiated) thyroid carcinoma:
 - Treatment should be similar to that of undifferentiated (anaplastic) thyroid carcinoma.
 - Survival:
 - Median survival 9 months
 - 3-year survival rate of 37.6%
 - Prognosis is very poor, but complete resection of disease may correlate with improved survival.
- In presence of squamous cell carcinoma in thyroid, a primary tumor originating elsewhere should be excluded:
 - Squamous carcinomas from mucosal site may directly invade into the thyroid or may metastasize to thyroid.
 - Rare collision tumors including papillary thyroid carcinoma and laryngeal squamous cell carcinoma reported

Mucinous Carcinoma

- Extremely rare characterized by clusters of neoplastic cells floating or surrounded by extracellular mucin deposition
- May present as either a slowly or rapidly growing lesion.
- Histologically similar to mucinous (colloid) carcinoma of other sites (e.g., breast, lung, salivary gland), including:

Fig. 28-90. Primary thyroid squamous cell carcinoma.

Left, tumor invading thyroid gland composed of solid interconnecting cords with foci of central necrosis. *Right*, At higher magnification the carcinoma is nonkeratinizing and has histologic features similar to nonkeratinizing carcinomas of the oro- and nasopharynx. In this case, the patient did not have a primary tumor in any other site. Material was unavailable to evaluate for human papillomavirus (p16) and Epstein-Barr virus (EBER).

Fig. 28-91. Squamous metaplasia versus SCC.

Histologic features of squamous cell metaplasia (in the setting of chronic lymphocytic [Hashimoto] thyroiditis) versus thyroid squamous cell carcinoma. *Left*, Squamous metaplasia is characterized by bland cytomorphology composed of rounded nests without invasive growth lacking nuclear pleomorphism and mitotic activity. *Right*, Squamous carcinoma is infiltrative and composed of cells with prominent nuclear pleomorphism and dyskeratosis.

- Presence of abundant mucoid lakes, within which are clusters of tumor cells
- Tumor cells composed of large nuclei with prominent nucleoli
- Mucinous material positive for mucicarmine
- Immunohistochemistry
 - Lesional cells are immunoreactive for thyroglobulin, TTF-1 (nuclear), cytokeratin (low molecular weight), and MUC3
 - Negative for carcinoembryonic antigen, calcitonin, and high-molecular-weight cytokeratin
 - Increased proliferation index by Ki67 (MIB1) staining (>10%)
 - p53 overexpression
- Must be differentiated from:
 - Other thyroid neoplasms with mucin production that may include:
 - Papillary carcinoma
 - Follicular carcinoma
 - Follicular adenoma
 - Medullary carcinoma
 - Mucoepidermoid carcinoma
 - Metastatic mucinous carcinomas from other organs
- Appears to have aggressive behavior with death from disease in months to years following diagnosis

Adenosquamous Carcinoma of Thyroid Gland (Fig. 28-92)

- Extraordinarily rare thyroid tumor
- Too few cases in literature to suggest any correlation to low-grade mucoepidermoid carcinoma.
- Spectrum of histologic types seen in the salivary glands (low-grade, intermediate-grade, and high-grade) not seen in the thyroid gland
- Histologically, these tumors include squamous cell carcinoma with glandular foci as well as mucocytes.
- Neoplastic infiltrate characterized by cells with obvious squamous differentiation (keratinization, intercellular bridges), pleomorphism, increased mitotic activity, and invasive growth
- Intracytoplasmic and intraluminal mucin-positive material may be identified.
- Foci of undifferentiated carcinoma can occur, such that this tumor has been considered as variant of an undifferentiated (anaplastic) thyroid carcinoma.
- High-grade malignancy with treatment and biologic behavior similar to that for undifferentiated (anaplastic) thyroid carcinoma
- In presence of adenosquamous carcinoma of thyroid gland, primary tumor originating in adjacent organ (larynx or trachea) should be excluded.

Fig. 28-92. Thyroid adenosquamous carcinoma.

A, The tumor is infiltrative and composed of solid nests (*upper left*) and glandular proliferation. **B**, *Left*, Undifferentiated carcinoma; *right*, glands and mucocytes; **C**, mucicarmine staining including (*left*) readily apparent intracytoplasmic and intraluminal mucin-positive material to (*right*) scattered mucin-positive cells.

NEUROENDOCRINE NEOPLASMS

- Thyroid neuroendocrine lesions/neoplasms include:
 - C-cell-related lesions:
 - C-cell hyperplasia
 - Medullary thyroid carcinoma
 - Mixed medullary and follicular cell neoplasms
 - Neuroendocrine carcinomas
 - Thyroid paraganglioma

C-CELL-RELATED LESIONS (C-CELL HYPERPLASIA AND THYROID MEDULLARY CARCINOMA)

See Chapters 26 and 27 for discussion of thyroid C-cells (parafollicular cells) and solid cell nests, respectively.

- C-cell-derived thyroid lesions include:
 - C-cell hyperplasia
 - Medullary thyroid carcinoma

C-Cell Hyperplasia (CCH)

(Figs. 28-93 through 28-95)

Definition: Multifocal quantitative increase in thyroid C-cells with replacement of thyroid follicles and follicular epithelial cells (see [Histology](#) below for further definitions).

- May more accurately be considered:
 - Pre-malignant proliferation or earliest phase in evolution of medullary thyroid carcinoma rather than non-neoplastic hyperplastic process
- Divided into reactive (“physiologic”) type and neoplastic type
- Reactive or “physiologic” CCH
 - Uncommon diffuse C-cell hyperplasia that may be difficult to identify by light microscopy
 - May occur in association with other diseases, including:
 - Hypercalcemia due to hyperparathyroidism
 - Hypercalcemia due to nonparathyroid causes

Fig. 28-93. Reactive C-cell hyperplasia.

A and B, At low magnification non-mass-forming nodular foci of C-cell hyperplasia seen around colloid-filled follicles (parafollicular) and appearing as smaller, darker nuclei devoid of colloid formation (*arrowheads*). **C,** C-cells are composed of round to oval nuclei with stippled chromatin and basophilic-appearing cytoplasm lacking significant nuclear atypia. **D,** C-cells show strong calcitonin immunoreactivity.

- Hypergastrinemia (Zollinger-Ellison syndrome)
- Adjacent to nonmedullary thyroid lesions (e.g., lymphocytic thyroiditis) and neoplasms (e.g., follicular adenoma, follicular carcinoma, papillary carcinoma)
- Neoplastic CCH
 - Appears as nodular foci associated with:
 - Hereditary medullary carcinoma, including:
 - Multiple endocrine neoplasia (MEN) syndromes (MEN-2A and MEN-2B)
 - Familial medullary carcinoma
- CCH may also be seen in association with phosphatase and tensin homolog deleted on chromosome ten (*PTEN*)-hamartoma tumor syndrome (PHTS):
 - Complex disorder caused by germline inactivating mutations of *PTEN* tumor suppressor gene
 - PHTS includes:
 - Cowden syndrome (CS)
 - Bannayan-Riley-Ruvalcaba syndrome (BRRS)
 - Proteus-like syndromes
 - Affected individuals develop benign and malignant tumors in a variety of tissues, including thyroid gland.
 - Thyroid pathology in PHTS includes:
 - Multiple adenomatous nodules in background of lymphocytic thyroiditis (75%)
 - Papillary thyroid carcinoma (60%), including:
 - Papillary microcarcinoma, follicular variant, classical type
 - C-cell hyperplasia (55%):
 - Nodular or diffuse
 - Lymphocytic thyroiditis alone (55%)

Fig. 28-94. Reactive C-cell hyperplasia.

A and B, In this example there is circumferential localization of C-cells around or encircling follicles (parafollicular).

C, C-cells are composed of round to oval nuclei with stippled chromatin lacking significant nuclear atypia. **D,** C-cells show strong calcitonin immunoreactivity.

- Follicular carcinoma (45%)
- Follicular adenoma (25%)
- Histologic criteria for CCH:
 - Based on cell count with no consensus
 - Various criteria include:
 - Clusters of more than 20 C-cells
 - More than 50 C-cells in one low-power field at a magnification of 100×
 - Increase in size and number of C-cells compared with age- and gender-matched controls (control groups normally having less than 10 C-cells per low-power field)
 - Above-cited criteria can be found in:
 - Normal thyroid glands, which may contain foci of up to 50 C-cells in a single low-power field
 - Nodules of C-cells may be seen in thyroid glands of older patients.
 - Around solid cell nests
 - Near to nonmedullary thyroid tumors
 - In association with chronic lymphocytic (Hashimoto) thyroiditis
- No specific criteria and/or markers assisting in differentiating reactive (physiologic) from neoplastic CCH, except perhaps for presence of nodular foci of CCH identifiable by light microscopy and confirmed by immunohistochemical staining, which support neoplastic proliferation

Reactive or “Physiologic” CCH

Clinical

- No specific demographics associated with reactive or physiologic CCH
- May or may not be associated with elevated serum calcium or calcitonin levels
 - Most patients with CCH do not have elevated basal levels of serum calcitonin but do have an

Fig. 28-95. Neoplastic C-cell hyperplasia (CCH).

A, Enlarged nodular focus readily identified at low magnification. **B**, Lesional cells composed of relatively uniform round to oval nuclei with stippled chromatin. **C**, Areas showing marked nuclear pleomorphism. Lesional cells are immunoreactive for **(D)** calcitonin and **(E)** synaptophysin. There are no established criteria assisting in differentiating nodular foci of neoplastic CCH from microscopic foci of medullary thyroid carcinoma (MTC); the images shown here could be interpreted as microscopic MTC but the absence of infiltrative growth, associated stromal sclerosis, and amyloid stroma even in the presence of nuclear pleomorphism support neoplastic CCH rather than microscopic MTC.

abnormal increase in serum calcitonin following provocative testing (calcium and/or pentagastrin stimulation testing)

- Patients with elevated basal calcitonin levels but whose values do not rise further following provocative testing should be retested after 3 months.
- Elevated levels of serum carcinoembryonic antigen (CEA) may be present.
- Exact mechanism for CCH identified adjacent to some thyroid follicular neoplasms is not known but may represent a reaction to chronic stimulation of gland by thyroid-stimulating hormone or a compensatory mechanism in response to destruction of gland by follicular tumor:
 - In support of these hypotheses is the fact that, in those cases with available tissue for study, CCH was limited to one lobe rather than multifocal and bilateral involvement as seen in MEN syndromes.

Pathology

Gross

- No specific macroscopic findings:
 - Without demonstrable mass

Histology

- Usually cannot be identified by light microscopy but requires immunohistochemical staining for identification, including:
 - Calcitonin
 - Synaptophysin or chromogranin
- Diffuse or focal proliferation, including:
 - Usually unilateral
 - Intrafollicular localization forming clusters within basement membrane of follicles surrounded by identifiable follicle
 - Circumferential localization around or encircling follicles:
 - Segmental within follicles
- Cytomorphologic features include:
 - Round to oval nuclei with stippled chromatin and basophilic-appearing cytoplasm
 - Not enlarged and lack (significant) nuclear pleomorphism or atypia

Differential Diagnosis

- Neoplastic CCH
 - *RET* protooncogene germline mutation:
 - Differentiates neoplastic (present) versus reactive/physiologic (absent) CCH
 - Evaluation of serum calcitonin levels does not differentiate patients with reactive (physiologic) from neoplastic C-cell hyperplasia.
- Solid cell nests
- Squamous metaplasia

- Intrathyroidal parathyroid tissue
- Intrathyroidal thymic tissue
- Palpation thyroiditis

Treatment and Prognosis

- Diagnosis of reactive (“physiologic”) C-cell hyperplasia generally can be treated medically with biochemical control.
- Excellent prognosis

Neoplastic CCH

Clinical

- Strongly associated with hereditary medullary thyroid carcinoma:
 - Usually present in association with MEN-2A, MEN-2B, and familial MTC alone
 - Usually absent in association with sporadic MTC
- May or may not be associated with elevated serum calcium or calcitonin levels:
 - Most patients do not have elevated basal levels of serum calcitonin but do have an abnormal increase in serum calcitonin following provocative testing with secretagogues for calcitonin, calcium, and pentagastrin.
 - Elevated levels of serum carcinoembryonic antigen (CEA) may be present.
- Patients with elevated basal calcitonin levels but whose values do not rise further following provocative testing should be retested after 3 months.

Pathology

Gross

- Generally, nondescript without a demonstrable mass lesion(s)

Histology

- Present diagnostic criteria for neoplastic CCH include:
 - Nodular or diffuse foci readily identifiable by light microscopy
 - Usually bilateral
 - Complete replacement/obliteration of follicle(s) with solid intrafollicular aggregates
- Cytomorphologic features include:
 - Enlarged cells with round to oval nuclei, stippled nuclear chromatin, and ample clear to pale-appearing cytoplasm
 - Mild to moderate nuclear pleomorphism or atypia
- Immunohistochemistry:
 - Calcitonin positive
 - Synaptophysin and chromogranin positive
 - Cytokeratin and CEA may be present.

- Thyroglobulin negative (except for those instances where the C-cell hyperplasia has not completely obliterated the follicular epithelial cells and thyroglobulin is seen within remnants of the follicular epithelium)
- Cytogenetics and molecular genetics:
 - Preferred diagnostic modality for hereditary form of medullary thyroid carcinoma rather than identifying C-cell hyperplasia and/or elevated serum calcitonin levels includes presence of:
 - *RET* protooncogene germline mutation:
 - Present in all cells of body
 - Present in tumor cells
 - Presence of *RET* mutation should prompt screening of family members as well as evaluation for other components of MEN syndrome (see Section 10).
 - Identification of C-cell hyperplasia in a patient whose thyroid has been removed for other reasons should initiate molecular testing for *RET* mutation.
 - Evaluation of serum calcitonin levels does not differentiate patients with reactive from neoplastic C-cell hyperplasia.

Differential Diagnosis

- Reactive (physiologic) CCH:
 - *RET* protooncogene germline mutation:
 - Differentiates neoplastic (*RET* present) versus reactive/physiologic (*RET* absent) CCH
 - Evaluation of serum calcitonin levels does not differentiate patients with reactive (physiologic) from neoplastic C-cell hyperplasia.
- Medullary thyroid carcinoma (MTC)—in particular, medullary microcarcinoma (microscopic MTC):
 - No established criteria assisting in differentiating nodular foci of neoplastic CCH from microscopic foci of MTC
 - Features supporting medullary microcarcinoma include:
 - Presence of nuclear pleomorphism
 - Presence of associated stromal sclerosis
 - Presence of amyloid stroma
 - Invasive growth
- Solid cell nests
- Squamous metaplasia
- Intrathyroidal parathyroid tissue
- Intrathyroidal thymic tissue
- Palpation thyroiditis

Treatment and Prognosis

- Neoplastic C-cell hyperplasia with *RET* germline mutation generally necessitates total thyroidectomy:
 - Thyroidectomy performed even in young patients (<10 years of age)

- Medullary thyroid carcinoma can be found in a large percentage of cases (>60%).
- Lymph node metastasis may be identified in small percentage of cases, and there may be a need for lymph node dissection (even in the young patient).
- Increased morbidity and mortality occur in MEN syndromes due to non-thyroid neoplasms or to medullary thyroid carcinoma but not as a result of CCH.

Medullary Thyroid Carcinoma (MTC) (Figs. 28-96 through 28-102)

Definition: Malignant thyroid neuroendocrine tumor with C-cell (parafollicular) differentiation.

Synonyms: C-cell carcinoma; solid carcinoma; solid amyloidotic carcinoma; neuroendocrine carcinoma of thyroid gland

Clinical

- Represents up to 5% to 10% of all thyroid neoplasms
- Occurs in two forms (Table 28-11):
 - Sporadic or nonfamilial MTC:
 - Represents approximately 70% to 80% of all cases
 - Unassociated with multiple endocrine neoplastic (MEN) syndrome
 - Hereditary MTC:
 - Represents approximately 20% to 30% of all cases
 - Associated with one of three clinical MEN syndromes, including:
 - MEN-2A
 - MEN-2B
 - Familial MTC
- All patients with diagnosis of MTC should be suspected of having genetic form of disease until proven otherwise.
- Sporadic MTC:
 - Most common form (70% to 80% of all cases)
 - Slightly more common in women than in men; primarily occur in older individuals (as compared to the familial form) with a mean age at diagnosis in the fifth to sixth decades of life
 - Clinical presentation
 - Unilateral palpable painless thyroid mass:
 - Bilaterality may occur in up to a third of patients.
 - Signs and symptoms may include:
 - Hoarseness, dysphagia, stridor
 - Incidence of cervical lymphadenopathy at presentation is high (40% to 50%).
 - Distant metastasis (lung, liver, bone) uncommon (approximately 12%)

Fig. 28-96. Medullary thyroid carcinoma, fine-needle aspiration biopsy.

A, Increased cellularity with single cells or small cell clusters including round to oval cells and a fragment of amyloid (*left*). **B** and **C**, Tumor cells are round to oval, polygonal, and/or plasmacytoid with round to oval, often eccentrically located, nuclei with stippled or coarse chromatin pattern and abundant granular eosinophilic cytoplasm with some showing metachromatic red (azurophilic) cytoplasmic granules (Diff-Quik). **D**, Calcitonin immunoreactivity confirms the diagnosis. The FNAB diagnosis would be "malignant; poorly differentiated carcinoma consistent with undifferentiated (anaplastic) thyroid carcinoma (Bethesda VI)."

Fig. 28-97. Medullary thyroid carcinoma.

Medullary thyroid carcinoma appearing as a solitary, circumscribed but focally infiltrative (*upper right*) tan-white and nodular thyroid mass.

- Patients with clinically evident MTC:
 - Almost always have elevated serum levels of calcitonin in basal state or following intravenous administration of secretagogues calcium or pentagastrin
 - Occasionally, serum calcitonin (and carcinoembryonic antigen) may not be elevated (non-secretory MTCs).
- Absence of germline mutation of *RET* protooncogene:
 - MTCs with somatic *RET* mutations (found only in tumor cells) present in one third to two thirds of cases of which:
 - 75% to 95% have replacement of methionine by threonine at codon 918
 - MTCs with *RET* somatic mutation as compared to those without mutation:

Fig. 28-98. Medullary thyroid carcinoma.

A, Infiltrative tumor including lesional cells invading into adjacent thyroid parenchyma; **(B)** lobular/organoid and **(C)** solid growth. Lesional cells include round to oval cells with round to oval and variably pleomorphic nuclei with coarse or stippled nuclear chromatin and basophilic to eosinophilic granular cytoplasm; **(D)** diffuse calcitonin reactivity. Additional immunoreactivity includes synaptophysin, chromogranin, and carcinoembryonic antigen (not shown).

- Higher frequency of regional lymph node and distant metastasis
- Tend to have worse prognosis:
 - Tumors with codon 918 appear to be more aggressive compared to other somatic *RET* mutations
- Presence of somatic *RAS* mutations:
 - Present in significant percentage of sporadic MTCs (>50%)
 - Only found in *RET*-negative sporadic MTCs
- Hereditary MTC:
 - Less common than sporadic MTC, representing 20% to 30% of all cases
 - Clinical presentation may correlate with pathologic features in other organs involved by MEN syndrome, including:
 - Adrenal gland, parathyroid, pituitary gland, gastrointestinal tract, pancreas
 - Germline mutation of *RET* protooncogenes present in 85% of families with hereditary MTC
 - Occurs in association with
 - MEN-2A
 - MEN-2B
 - Familial MTC
- MTC in association with MEN-2A (multiple endocrine adenomatosis 2 [MEA2]; Sipple syndrome):
 - Most common of three subtypes, accounting for 75% to 90% of familial cases
 - Characterized by presence of:
 - MTC
 - Pheochromocytoma (approximately 50%)

Fig. 28-99. Amyloid in MTC.

Left, Medullary thyroid carcinoma with associated amyloid deposition appearing on hematoxylin and eosin stain sections as acellular, eosinophilic-appearing material. *Right*, Congo red stain demonstrating classic apple-green birefringence of the amyloid as seen under polarization.

- Primary parathyroid hyperplasia (20% to 30%)
 - Rare cases associated with Hirschsprung disease and cutaneous lichen amyloidosis
- Autosomal dominant pattern of inheritance
- Slightly more common in women than in men; mean age at diagnosis is in the third to fourth decades of life
- MTC usual first manifestation of syndrome
- Clinical presentation:
 - Slow-growing, painless thyroid mass
 - Multicentric and bilateral in more than 90% of cases
 - Incidence of cervical lymphadenopathy at presentation is low (<15%).
 - Distant metastasis (lung, liver, bone) is rare (<3%).
- Germline mutation of *RET* protooncogene
 - Usually involve exon 10 and 11
 - Most common genetic abnormality found in 95% of families with MEN-2A
 - Genetic testing for *RET* protooncogene has largely replaced serum calcitonin measurement for diagnosis of hereditary MTC.
- MTC in association with MEN-2B (MEN-2B, MEN-3, Wagenmann-Froboese syndrome):
 - Least common of three subtypes, accounting for approximately 5% of familial cases
 - Characterized by presence of:
 - MTC
 - Pheochromocytoma (approximately 50%)
 - Mucosal neuroma and gastrointestinal ganglioneuromatosis (100%)
 - Marfanoid appearance (100%)
 - Rarely associated with parathyroid hyperplasia
 - Autosomal dominant pattern of inheritance
 - Slightly more common in women than in men; mean age at diagnosis is in second decade of life:
 - Usually presents in patients <10 years of age
 - May even occur in neonatal period
 - Clinical presentation:
 - Painless thyroid mass
 - In addition, these patients have:
 - Mucosal neuromas (oral mucosa, lips, tongue, eyelids)
 - Ganglioneuromatosis of the gastrointestinal tract
 - Children with MEN-2B may present with clinical picture identical to Hirschsprung disease: rectal biopsy reveals proliferation rather than absence of ganglia.
 - Skeletal deformities including Marfan-like habitus, pes cavus
 - Multicentric and bilateral in more than 90% of cases
 - Incidence of cervical lymphadenopathy at presentation is approximately 38%.
 - Development of distant metastasis (lung, liver, bone) in approximately 20%
- Germline mutation of *RET* protooncogene:
 - Point mutation at exon 16:
 - Replacement of methionine by threonine at codon 918
 - Identified in 95% of cases with MEN-2B
- Genetic testing for *RET* protooncogene has largely replaced serum calcitonin measurement for diagnosis of hereditary MTC.
- Familial MTC (MTC alone):
 - Second most common of three subtypes, accounting for approximately 15% of familial cases
 - Not associated with lesions of other organs (hence designation as MTC alone)
 - Autosomal dominant pattern of inheritance
 - Slightly more common in women than in men; mean age at diagnosis is in fifth to sixth decades of life
 - Clinical presentation:
 - Painless thyroid mass
 - Multicentric and bilateral in more than 90% of cases
 - Incidence of cervical lymphadenopathy at presentation is 10% to 20%
 - Distant metastasis (lung, liver, bone) rarely, if ever, occurs.

Fig. 28-100. Medullary thyroid carcinoma.

Medullary thyroid carcinoma may show **(A)** lobular or insular growth; **(B)** foci of confluent necrosis and **(C)** increased mitotic activity (*arrowheads*). Such features might suggest a diagnosis of a poorly differentiated thyroid carcinoma but the presence of **(D)** calcitonin reactivity as well as synaptophysin and chromogranin (not shown) coupled with absence of thyroglobulin and TTF-1 (not shown) would be diagnostic for medullary thyroid carcinoma.

- Germline mutation of *RET* protooncogene:
 - 85% of families show mutations in codons of exons 10 and 11.
 - Mutations in codons 768, 790, 791, 804, 848, 883, 891, 904
- Genetic testing for *RET* protooncogene has largely replaced serum calcitonin measurement for diagnosis of hereditary MTC.
- Testing:
 - First-degree relatives of patients affected by a familial form of MTC should undergo genetic evaluation to determine if they also have genetic evidence (i.e., *RET* protooncogene mutations) indicative of familial TMC.
 - Genetic evidence of familial TMC guides therapy (see below).

Fig. 28-101. Histologic variant of medullary thyroid carcinoma.

Histologic variants of medullary thyroid carcinoma may include **(A and B)** spindle cell and **(C and D)** papillary. These variants were confirmed by immunohistochemical staining for calcitonin and neuroendocrine markers and absence of thyroglobulin and TTF-1 (not shown).

- Once a family member has been diagnosed with MEN syndrome, all at-risk family members should be screened.
- Testing should be performed annually until age of 30, at which time more than 90% of all MEN gene carriers are detected by screening methods.
- Additional signs and symptoms may include:
 - Paraneoplastic syndromes owing to production of bioactive peptides and amines, including:
 - Severe watery diarrhea (10% to 30%)
 - Flushing, carcinoid syndrome
 - Renal stones, hypertension
 - Cushing disease owing to secretion of adrenocorticotrophic hormone (ACTH) may rarely occur in association with primary or metastatic MTC.
- Radiology
 - Radionuclide imaging:
 - Hypofunctioning (“cold”) nodule
 - Ultrasound:
 - Solid mass
 - MTC does not concentrate radioiodine.
- Imaging with ^{131}I metaiodobenzylguanidine (MIBG) useful tool in diagnosis
 - ^{131}I MIBG is guanethidine analog used in detection of neoplasms of neural crest origin
 - Many neural crest-derived tumors (including medullary thyroid carcinoma and pheochromocytoma) belong to dispersed neuroendocrine system (DNES), formerly known as the amine precursor uptake and decarboxylase (APUD) system, and sequester norepinephrine into intracellular granules.
 - MIBG is structurally similar to norepinephrine and competes with norepinephrine for uptake and storage in chromaffin granules within adrenergic cells.
 - Uptake of MIBG not dependent on ability of a tumor to actively synthesize and secrete catecholamines
- Plain film of the neck:
 - May reveal dense calcification considered a feature of this tumor

Fig. 28-102. Atypical or calcitonin-poor medullary thyroid carcinoma.

A, Cellular thyroid tumor with capsular invasion. **B**, Lobular and solid growth with fibrovascular stroma. **C**, Cytomorphologic features are similar to those seen in typical medullary thyroid carcinomas. Immunohistochemical staining shows **(D)** absence of calcitonin but **(E)** presence of synaptophysin. In addition, immunoreactivity is present for chromogranin, NSE, and CEA (not shown) with absence of thyroglobulin and TTF-1 reactivity (not shown).

TABLE 28-11 Forms of Medullary Thyroid Carcinoma

	Sporadic (Nonfamilial)	MEN-2A	MEN-2B	Familial MTC
Synonym(s)		Multiple endocrine adenomatosis 2 (MEA2); Sipple syndrome	MEN-3; Wagenmann- Froboese syndrome	MTC alone
Percentage of cases of MTC	80%	Approximately 75% to 90% of familial cases	Approximately 5% of familial cases	Approximately 15% of familial cases
Gender/age	F > M; 5th-6th decades	Slight F > M; 3rd-4th decades and younger	Slight F > M; infancy and early childhood (1st-2nd decades)	Slight F > M; 5th-6th decades of life
Inheritance	Noninherited	Autosomal dominant	Autosomal dominant	Autosomal dominant
Germline RET proto-oncogene mutation	Absent; somatic <i>RET</i> mutations (found only in tumor cells) present in $\frac{1}{3}$ to $\frac{2}{3}$ of cases 75% to 95% have replacement of methionine by threonine at codon 918	Present; usually involve exon 10 and 11; most common genetic abnormality found in 95% of families with MEN-2A	Present; point mutation at exon 16 (codon 918); identified in 95% of cases with MEN-2B	Present; 85% of families show mutations in codons of exons 10 and 11
Associated lesions	None; CCH usually absent but may be present near tumor	CCH; pheochromocytoma; primary hyperparathyroidism with parathyroid proliferative disease (adenoma; hyperplasia)	CCH; pheochromocytoma; oral mucosal neuromas; ganglioneuromatosis of intestines; marfanoid habitus; medullated corneal nerve fibers	CCH
Bilateral tumor	Usually unilateral; may be bilateral in up to 33% of patients	>90%	>90%	>90%
Treatment	Total thyroidectomy	Total thyroidectomy	Total thyroidectomy	Total thyroidectomy
Metastasis	LN: 40% to 50% (at presentation) Distant: 12%	LN: <15% (at presentation) Distant: rare (<3%)	LN: 38% (at presentation) Distant: 20%	LN: 10% to 20% (at presentation) Distant: 0
Prognosis	Indolent course with: 5-year survival rates of 70% to 80% 10-year survival rates of 50% to 75% 15-year survival rates of 65%	Indolent course with much lower tumor-related mortality rates as compared to MEN-2B	More aggressive with early dissemination and increased tumor-related deaths	Least aggressive with no tumor- related deaths

CCH, C-cell hyperplasia; LN, lymph nodes; MTC, medullary thyroid carcinoma.

Pathology

Fine-Needle Aspiration Biopsy

- Cytologic variability from case to case, reflecting histologic variability
 - Increased cellularity with single cells or small (syncytial) cell clusters
 - Tumor cells vary and include:
 - Round to oval, spindle-shaped, polygonal, and/or plasmacytoid cells
 - Round to oval often eccentrically located nuclei with stippled or coarse chromatin pattern
 - Intranuclear inclusions occasionally present:
 - Nucleoli usually inconspicuous but may be prominent
 - Binucleate and multinucleate cells are common.
 - Mild to moderate nuclear pleomorphism
 - Nuclear grooves typically absent
 - No significant increase in mitotic activity
 - Abundant granular eosinophilic cytoplasm:
 - Distinct metachromatic red (azurophilic) cytoplasmic granules
 - Seen in air-dried preparations stained with Romanowsky method and not in Papanicolaou stained preparations

- Present in approximately 5% to 10% of cases
- Correspond to neurosecretory granules
- Extracellular homogeneous eosinophilic to pale orange, amorphous clumps, spheres, or rods can be seen and correspond to amyloid.
 - Congo red staining can confirm presence of amyloid.

Gross

- Sporadic tumors:
 - Typically unilateral, solitary lesions
- Hereditary tumors:
 - Usually multifocal and bilateral
- Usually identified in middle aspects of lateral lobe(s)
 - Represents areas of greatest concentration of C-cells
 - Isthmic involvement occurs secondarily from large tumor originating in lateral lobe(s).
- Variability in size, including:
 - Barely visible to large tumors occupying a part or entire affected lobe
- May be encapsulated:
 - Larger tumors tend to be well delineated or circumscribed but not encapsulated.
 - Some tumors have infiltrative growth.
- On sectioning, tan-white, yellow, gray, or pink varying in consistency from soft to rubbery to firm:
 - Hemorrhage and necrosis not usually present but calcifications can be appreciated

Histology

- Histologic features variable from case to case; however, irrespective of clinical setting in which MTC occurs (i.e., sporadic versus hereditary), histology is similar.
- Vary from circumscribed to encapsulated to unencapsulated to infiltrative
 - Extension of the tumor into adjacent thyroid parenchyma is often present.
- Growth patterns include:
 - Organoid, lobular, trabecular, solid, insular, or sheet-like:
 - Cell nests separated by a highly (fibro)vascular stroma
 - Less often, may exhibit pseudopapillary, follicular, glandular, or cribriform growth patterns
- Cytomorphologic features include:
 - Round to oval to spindle-shaped to plasmacytoid cells
 - Round to oval nuclei with coarse or stippled chromatin
 - Nuclei may be eccentrically situated, resulting in plasmacytoid appearance but paranuclear

clear zone or “hof” typical of plasma cells is not present.

- Nucleoli usually inconspicuous
- Intranuclear pseudoinclusions can be seen.
- Binucleate and multinucleate cells common
- Ill-defined cytoplasm with basophilic to eosinophilic to amphophilic and granular
- Clear cell changes may be seen.
- Mild to moderate nuclear pleomorphism and mitotic figures can be seen but, in general, no significant pleomorphism or increase in mitotic rate.
- Necrosis and hemorrhage not characteristically present
- Calcification and psammoma bodies (with concentric laminations) may be identified.
- A prominent neutrophilic cell infiltrate may occasionally be present.
- Stromal amyloid:
 - Seen in up to 85% of cases
 - Appears as homogeneous, acellular, eosinophilic bands or nodules
 - May be focally present or may be diffuse, almost completely replacing tumor
 - Associated calcifications and foreign body giant cell reaction may be identified.
 - In some cases no associated amyloid deposition
 - Multinucleated giant cells may be present in association with amyloid, and amyloid can be seen within cytoplasm of multinucleated giant cells.
- Colloid-filled follicles can be seen within tumor:
 - Not an indication of dual C-cell and follicular differentiation
 - Represent remnants of follicular epithelium entrapped by MTC
- Invasive growth may be present and includes:
 - Extension into adjacent thyroid parenchyma
 - Angioinvasion
 - Extrathyroidal invasion into perithyroidal soft tissue and/or into adjacent organs (e.g., larynx, trachea, esophagus)
- C-cell hyperplasia in association with MTC:
 - Strongly associated with hereditary medullary thyroid carcinoma:
 - Usually present in association with MEN-2A, MEN-2B, and familial MTC alone
 - Typically present either adjacent to or separate from MTC
 - Usually absent in association with sporadic MTC
- Histologic variants of MTC (Box 28-7):
 - Irrespective of variant, nuclear features and immunohistochemical staining associated with typical MTC are present.
 - Generally no prognostic significance identified in association with MTC variants

BOX 28-7 Histologic Variants of Medullary Thyroid Carcinoma

- Classic or conventional type (organoid)
- Medullary microcarcinoma
- Spindle-shaped
- Oncocytic
- Papillary
- Glandular/tubular (follicular)
- Giant cell (anaplastic)
- Small cell (neuroblastoma-like)
- Carcinoid-like
- Hyalinizing trabecular adenoma-like
- Paraganglioma-like
- Angiosarcoma-like
- Squamous cell
- Clear cell
- Mucin producing
- Pigmented or melanin-producing
- Atypical (“calcitonin poor”)
- Mixed medullary-follicular carcinoma or medullary-papillary carcinoma

- Medullary microcarcinoma:
 - Measures <1 mm in greatest dimension
 - Common in thyroids prophylactically excised owing to presence of *RET* germline mutation but can be identified in sporadic MTCs
 - May be multifocal and bilateral
 - May be associated with elevated serum basal calcitonin levels
 - Histologic features similar to MTC:
 - May show features seen in other histologic variants (see below)
 - Characterized by complex microarchitectural pattern, desmoplastic stromal response, and (focal) amyloid deposition
 - May be associated with:
 - Extrathyroidal extension (approximately 8%)
 - Regional lymph node metastasis (20% to 30%) and may be related to size:
 - Medullary microcarcinomas measuring ≤5 mm associated with a probability of lymph node metastases of approximately 23%; probability increased in patients with tumors >5 mm
 - Distant metastasis (approximately 5%)
 - Rarely may present with distant (e.g., lung) metastasis
 - Overall 10-year survival rates for patients with localized, regional, and distant disease stages include 96%, 87%, and 50%, respectively
 - Extrathyroid extension and tumor size retain independent association with lymph node metastases.
- Differentiation from neoplastic CCH may be problematic:
 - No established criteria assisting in differentiating nodular foci of neoplastic CCH from microscopic foci of MTC
 - Features supporting medullary microcarcinoma include:
 - Presence of nuclear pleomorphism
 - Presence of associated stromal sclerosis
 - Presence of amyloid stroma
 - Invasive growth
- Spindle cell:
 - Dominated by and/or exclusively composed of spindle-shaped cells:
 - Spindle-shaped cells are commonly seen in usual MTC.
 - Dominant component in approximately 20% of cases
- Oncocytic:
 - Partly or entirely composed of cells with oncocytic cytoplasmic change
 - May resemble oncocytic (Hürthle cell) follicular epithelial cell neoplasms, including presence of prominent eosinophilic nucleoli
 - Histologic findings that may assist in differentiating oncocytic MTC from oncocytic follicular epithelial cell neoplasms include presence of:
 - Amphophilic rather than brightly eosinophilic cytoplasm
 - Tumor nests divided by sharply outlined fibrous stroma
 - Immunohistochemical findings (see below) allow for differentiation but histologic similarities to oncocytic follicular epithelial cell neoplasms may result in erroneous light microscopic diagnosis without consideration for performing immunohistochemical staining.
- Papillary or pseudopapillary:
 - Artifactual separation of lesional cells results in pseudopapillae.
 - Uncommonly, true papillary architecture may be present.
- Glandular (tubular) or follicular:
 - Rare variant
 - Characterized by presence of follicles that may appear empty or contain eosinophilic secretions
 - May also show solid and trabecular growth patterns
- Giant cell (anaplastic):
 - Presence of predominant population of large cells with marked pleomorphism, bizarre-appearing nuclei, and nuclear pseudoinclusions:
 - May be multinucleated or multilobulated

- No significant increase in mitotic activity
- Foci of conventional MTC may be present.
- Small cell or neuroblastoma-like:
 - Characterized by presence of small cells with hyperchromatic nuclei and scant cytoplasm with sheet-like, trabecular, or nodular growth
 - Increased mitotic activity and necrosis may be present.
 - Foci of more typical MTC may be identified but may require extensive sampling.
 - Immunoreactive for calcitonin, synaptophysin, chromogranin, and cytokeratins:
 - Some cases reported to be calcitonin negative
- Carcinoid-like:
 - Presence of organoid, trabecular, or glandular growth separated by fibrovascular stroma simulate appearance of typical carcinoid
- Hyalinizing trabecular tumor-like:
 - Encapsulated MTC showing organoid and trabecular pattern with hyalinized stroma composed of polyhedral to spindled tumor cells with hyaline-appearing cytoplasm
- Paraganglioma-like:
 - Organoid or nested growth similar to paraganglioma
 - S100 protein positive peripherally situated sustentacular cells identified
- Angiosarcoma-like or pseudoangiosarcomatous
 - Presence of cellular dehiscence with associated hemorrhage may result in cleft-like or pseudo-vascular spaces simulating angiosarcoma.
 - Staining for endothelial markers (e.g., CD31, CD34, Factor VIII-related antigen, Fli1, ERG) negative
- Squamous cell:
 - Rarely, squamous differentiation reported
- Clear cell:
 - Rare variant
 - Focally or entirely composed of cells with clear-appearing cytoplasm
- Mucin-producing:
 - Also referred to as amphicrine-composite calcitonin producing
 - Presence of signet ring or goblet cells containing mucin
 - Ultrastructural findings include presence of neurosecretory granules and glandular feature.
- Pigmented or melanin-producing:
 - Rare cases show presence of intracytoplasmic melanin
- Atypical (“calcitonin poor”) medullary thyroid carcinoma:
 - Histologic features of typical MTC with immunoreactivity for neuroendocrine markers (i.e., synaptophysin and chromogranin), NSE and CEA but absent to very little calcitonin staining, absence of thyroglobulin, and TTF-1:
 - May be classified as nonmedullary neuroendocrine carcinoma of thyroid (see below)
- Histochemistry:
 - MTC cells:
 - Argyrophilic (Grimelius stain) but less often are argentaffinic (Fontana-Masson stain)
 - Intra- and extracellular periodic acid Schiff (PAS), alcian blue, and mucicarmine positive staining can be seen.
 - Melanin pigment may be found by argentaffin stains (Fontana-Masson).
 - Amyloid:
 - Congo red imparts an apple-green birefringence in polarized light.
 - Crystal violet imparts metachromatic appearance.
- Immunohistochemistry:
 - MTC cells:
 - Calcitonin most sensitive and specific marker:
 - Present in >95% of cases
 - May be negative representing either:
 - Atypical (“calcitonin poor”) medullary thyroid carcinoma
 - Nonmedullary neuroendocrine carcinoma of thyroid
 - Synaptophysin and chromogranin positive
 - Thyroid transcription factor-1 (TTF-1) reactivity (nuclear) variably present from case to case, including:
 - Focal and weak to diffuse and intense nuclear staining
 - Carcinoembryonic antigen reactivity:
 - Sensitive but not specific marker
 - Cytokeratins (AE1/AE3, CAM 5.2, CK7) present:
 - CK20 negative
 - Additional markers that may be positive (but generally unnecessary in diagnosis) include:
 - Neuron-specific enolase (NSE), calcitonin gene-related peptide (CGRP), somatostatin, ACTH, bombesin, Leu-enkephalin, serotonin, insulin, glucagon, gastrin, vasoactive intestinal peptide (VIP), substance P, human chorionic gonadotropin, and others
 - PAX8 (nuclear) may be positive.
 - S100 protein staining:
 - May show preferential peripheral sustentacular-like pattern:
 - Noted in association with familial MTC but not sporadic MTC
 - Thyroglobulin negative
 - Amyloid:
 - Positive reactivity with amyloid A (AA) antibody

- Electron microscopy:
 - Membrane-bound neurosecretory granules
 - Characteristic ultrastructural feature
 - Shown to contain calcitonin
 - Granules been divided into larger granules (type I) and smaller granules (type II), measuring on average 280 nm and 130 nm, respectively
- Cytogenetics and molecular genetics:
 - See [Clinical](#) section above.

Differential Diagnosis

- Hyalinizing trabecular tumor
- Follicular adenoma
- Follicular carcinoma
- Papillary thyroid carcinoma
- Paraganglioma (see below)
- Non-thyroid neuroendocrine carcinomas especially from larynx (i.e., moderately differentiated neuroendocrine carcinoma or atypical carcinoid):
 - Metastatic tumors to cervical lymph nodes may occur in absence of a known primary tumor.
 - Histologic and immunohistochemical features are typical for a neuroendocrine carcinoma, including immunoreactivity for calcitonin (>80%) as well as synaptophysin, chromogranin, cytokeratins, and CEA.
 - In this scenario, MTC is leading diagnosis but a neuroendocrine carcinoma from mucosal sites of head and neck especially from the (supraglottic) larynx may demonstrate identical histologic features and immunohistochemical staining pattern as MTC.
 - Differentiation based on serum calcitonin and/or TTF1 staining:
 - Most important diagnostic test is presence or absence of elevated serum calcitonin levels:
 - MTC almost invariably associated with elevated serum calcitonin levels
 - Upper aerodigestive tract (e.g., larynx) mucosal neuroendocrine tumors not associated with elevated serum calcitonin levels
 - Diffuse TTF-1 (nuclear) reactivity reported in MTC but absent in laryngeal moderately differentiated neuroendocrine carcinoma
- Amyloid goiter
- Malignant lymphoma
 - During surgery, parathyroid glands identified and, if enlarged, excised
- Prophylactic total thyroidectomy and neck dissection in MTC:
 - Recommended in patients with germline *RET* mutations including children under 3 years of age
 - Recommended for children with MEN-2B:
 - Total thyroidectomy and lymph node dissection performed in first month of life or as soon as phenotype identified:
 - Most cases of MEN-2B are de novo phenotype, most commonly identified in 3- to 10-year age period.
 - In such children surgical cure is uncommon.
 - Relative aggressiveness of MTC associated with specific *RET* mutations, including:
 - Presence of codon 918 mutation:
 - Indicative of aggressive disease phenotype whether mutation is hereditary (MEN-2B) or acquired as somatic mutation
 - Surgery performed in first month of life or as soon as phenotype identified
 - Presence of codon 634 *RET* mutation:
 - Aggressive phenotype accounting for approximately 80% of hereditary MTC
 - Surgery performed <5 years of age
 - Presence of mutations of codons 768, 790, 791, and 804:
 - In certain kindreds these mutations associated with metastasis and deaths
 - In other kindreds these mutations never associated with deaths
 - Consideration for surgery <5 years of age or delay in following criteria met:
 - ◻ Less aggressive family history
 - ◻ Normal serum calcitonin
 - ◻ Normal neck ultrasound
 - Prophylactic thyroidectomies in above situations may not show macroscopic tumor:
 - CCH and/or medullary microcarcinoma(s) may be seen by histologic evaluation aided by calcitonin immunohistochemical staining.
- Regional lymph node dissection in MTC
 - Metastatic disease to regional lymph nodes occurs early in disease course, warranting neck dissection, including:
 - Prophylactic central lymph node dissection indicated as part of the initial therapeutic management
 - Central lymph node dissection includes nodes from hyoid bone to innominate vein
 - Lateral neck dissection:
 - Patients with palpable thyroid tumors often have metastatic tumor to lateral cervical lymph nodes.

Treatment and Prognosis

- Preferred treatment for all forms of MTC may include:
 - Total thyroidectomy
 - Lymph node resection

- Modified or radical neck dissection reserved for those patients with jugular node metastasis (sampled intraoperatively) or disease that invades jugular veins or sternocleidomastoid muscles.
 - Metastatic disease may occur at an early age, including within first decade of life.
 - Metastatic disease (even at presentation) may occur even in presence of encapsulated MTC.
- Distant metastasis:
 - Less frequently, distant metastasis to liver, lungs, bone, and adrenal glands may occur.
- Local recurrence:
 - May occur in up to one third of patients following treatment
- Other therapeutic modalities may include:
 - Standard chemotherapy and radiation therapy (external, radioactive iodine)
 - Not been shown to be effective in treatment of MTC
 - Not radiosensitive tumor
 - Radiotherapy can be used for those patients with inoperable disease and whose tumor may be compressing and compromising vital structures (trachea, esophagus, large vessels).
 - No effective chemotherapeutic regimens for MTC
 - Radioactive iodine therapy does not play a role in management because neoplastic cells do not uptake iodine and therefore ablative therapy does not work.
 - Targeted drug therapies:
 - Promising and being examined in therapeutic clinical trials
 - Kinase inhibitor therapy:
 - Vandetanib or cabozantinib may be recommended for select patients with metastatic MTC.
- Postoperative management of MTC may include:
 - Monitoring of serum calcitonin and carcinoembryonic antigen (CEA) levels:
 - Serum calcitonin measurement:
 - Used to follow patients with residual or metastatic disease
 - Sequential measurements over extended periods useful for quantitating tumor mass:
 - Almost direct correlation between calcitonin measurements and tumor volume
 - Points regarding serum calcitonin measurement:
 - Secretion of calcitonin is episodic and affected by ambient plasma calcium concentration, exercise, eating (gastrin stimulation)
 - May normally vary by factor 2- to 3-fold, so direct comparison of any two measurements provides little useful information
 - Aggressive MTCs paradoxically lose ability to transcribe CT/CGRP gene such that falling calcitonin levels may be an indicator of poor prognosis.
 - Patients with serum calcitonin levels >5000 pg/ml (normal usually <10 pg/ml) following total thyroidectomy and lymph node dissection most commonly have metastatic disease outside neck region; in such patients presence of disease almost always detected by imaging (e.g., ultrasound, CT scan) of chest or abdomen; if radiologic imaging is negative, metastasis may be present in liver, a location where microscopic metastases may be difficult to detect.
 - CEA measurements:
 - Less short-term variability of plasma concentrations than for calcitonin
 - Useful for monitoring tumor mass
 - Insensitive and inaccurate marker for detecting early MTC owing to fact that:
 - May be elevated in cigarette smokers
 - May be elevated in association with other tumor types
 - Has broad range of normality
 - Stable CEA levels with or without changes in calcitonin levels suggests stable or slowly progressive disease
 - Rapidly rising CEA levels (with or without rapidly rising calcitonin levels):
 - Suggests emergence of more aggressive tumor
 - More aggressive behavior may be associated with persistently elevated CEA levels in association with decreasing calcitonin levels in serum and tissue.
- Prognosis (approximately):
 - 5-year survival rates are 70% to 80%.
 - 10-year survival rates are 50% to 78%.
 - 15-year survival rates are 65%.
- Prognostic factors:
 - Clinical stage (see [Table 28-6](#)):
 - Most important prognostic factor
 - Tumors confined to thyroid without evidence of metastatic disease have an excellent prognosis, with almost 100% cure rates following surgery.
 - Earlier detection (smaller tumor, lower stage), better survival:
 - Patients whose thyroid lesion or tumor is discovered in screening process for familial disease usually have C-cell hyperplasia or small neoplastic foci and have an excellent prognosis following surgery.

- Tumors larger than 1 cm have an unfavorable prognosis.
- Patients whose tumors are not totally excised or who have distant metastasis or who have elevated postoperative calcitonin or carcinoembryonic antigen (CEA) levels have a less favorable prognosis:
 - Even in this group there is variability in outcome, with some patients surviving for long periods of time, whereas others succumb to disease in relatively short time frames.
- 5-year observed and relative survival rates per stage include:
 - Stage I: 100% and 100%
 - Stage II: 88% and 98%
 - Stage III: 74% and 81%
 - Stage IV: 25% and 28%
- Age/gender:
 - Patients under 40 years of age have a better prognosis.
 - Patients older than sixth and seventh decades have a worse prognosis.
 - Women have better prognosis than men.
- Hereditary versus sporadic:
 - In decreasing order (best to worst) survival patterns of MTC are:
 - Familial (non-MEN) > sporadically or in association with MEN-2A > MEN-2B
 - MEN-2B-associated MTC are aggressive tumors with early dissemination and increase in tumor-related deaths.
- Calcitonin and CEA:
 - Calcitonin-rich tumors (>75% of cells) associated with better prognosis than calcitonin-poor tumors (<25% of cells):
 - Upon recurrence or relapse, calcitonin-rich tumors may become calcitonin poor.
 - Survival statistics do not necessarily apply for longer periods of time (beyond the 5-year range).
 - Biochemical cure defined as normal serum calcitonin levels is associated with good survival rates (10-year survival of 98%).
 - Inability to achieve a biochemical cure associated with worse survival rates (10-year survival of 70%)
 - Decreased calcitonin immunoreactivity coupled with increased CEA reactivity reported to be associated with worse prognosis
- Pathologic factors other than calcitonin and CEA immunoreactivity that may (but not consistently) correlate with prognosis include:
 - Tumor size:
 - Smaller tumor, better prognosis

- Encapsulation:
 - Encapsulated tumors have more favorable prognosis
- Extrathyroidal extension:
 - Invasion beyond thyroid gland equates to higher tumor stage and worse prognosis
- Histologic type:
 - Small cell type (if it exists) purportedly a more aggressive tumor
- Amyloid content:
 - More amyloid content associated with better prognosis further enhanced by presence of calcification
 - Amyloid free/poor tumors may behave more aggressively than amyloid.
- Pleomorphism, increased mitotic activity, and necrosis:
 - Associated with worse prognosis

MIXED MEDULLARY-FOLLICULAR CARCINOMA (FOLLICULAR-PARAFOLLICULAR CARCINOMA) AND MIXED MEDULLARY-PAPILLARY CARCINOMA

- Controversial tumor category
- Defined as:
 - Neoplasm in which there is an admixture of medullary thyroid carcinoma characterized by typical morphologic features and immunoreactivity for calcitonin with one of the following:
 - Thyroid follicular carcinoma characterized by an invasive carcinoma with colloid-filled follicles and immunoreactivity for thyroglobulin
 - Papillary thyroid carcinoma characterized by a neoplasm with characteristic nuclear features and immunoreactivity for thyroglobulin
- Although evidence supports existence of these tumor types, they are rare and a more common occurrence is not “dual” differentiation but either:
 - Presence of medullary thyroid carcinoma with entrapped non-neoplastic thyroid follicular epithelium with diffusion of thyroglobulin from surrounding thyroid tissue or
 - Collision tumor, including:
 - Separate and/or colliding foci within same gland of medullary thyroid carcinoma and:
 - Papillary thyroid carcinoma
 - Follicular carcinoma
- Evidence to support existence of a true mixed neoplasm includes:

- Some cases reported to be familial
- Immunoreactivity for calcitonin and thyroglobulin in MTC and follicular carcinoma components, respectively
- Ultrastructural findings include presence of neurosecretory granules and cells with follicular differentiation.
- Most compelling evidence to support existence of such a tumor type would be metastatic disease that includes foci of MTC and thyroid follicular cell-derived tumor (follicular carcinoma or papillary thyroid carcinoma) by light microscopic and immunohistochemical staining.
- Treatment and biologic behavior controversial given too few cases in literature but suggestion that treatment protocols follow those of MTC

THYROID NEUROENDOCRINE CARCINOMAS (OTHER THAN MTC) (see Fig. 28-102)

- Controversial category that may include atypical or calcitonin-poor medullary thyroid carcinoma or nonmedullary neuroendocrine carcinoma
- Atypical or calcitonin-poor medullary thyroid carcinoma (also referred to as C-cell derived calcitonin-free neuroendocrine carcinoma) characterized by tumor with:
 - Architectural and cytomorphology of neuroendocrine carcinoma
 - Chromogranin, synaptophysin, and neuron-specific enolase reactivity
 - Absence or near absence of calcitonin reactivity
 - Presence of calcitonin gene-related peptide (CGRP):
 - Supportive evidence of C-cell derivation
 - Absence of thyroglobulin
 - May be reactive for TTF-1, PAX8
 - Reactive for cytokeratins (AE1/AE3 and CK8/18),
 - One case in literature reported:
 - In situ hybridization lacked expression for calcitonin and thyroglobulin mRNA
 - Genetic analysis negative for *RET* mutation
- Nonmedullary neuroendocrine carcinoma of thyroid characterized by:
 - Architectural and cytomorphology of neuroendocrine carcinoma
 - Expression of thyroglobulin (and TTF-1), synaptophysin, and chromogranin
 - Absence of calcitonin staining
 - Expression of thyroglobulin and TTF-1 would support derivation from follicular epithelial cells rather than C-cells.
- In theory, spectrum of neuroendocrine carcinomas (NEC) seen in other organs may occur in thyroid, but in reality such tumor types occurring in thyroid gland are extremely rare.
 - Classification of NEC includes:
 - Carcinoid tumor (well-differentiated neuroendocrine carcinoma)
 - Atypical carcinoid (moderately differentiated neuroendocrine carcinoma)
 - Small or large cell neuroendocrine carcinoma (poorly differentiated neuroendocrine carcinoma)
 - Of above thyroid small cell neuroendocrine carcinoma reported:
 - Rare tumor type
 - Histologically similar to small cell neuroendocrine carcinoma of more common sites (i.e., lung)
 - Immunohistochemistry:
 - Cytokeratin, chromogranin, synaptophysin, TTF-1 positive
 - Calcitonin negative
 - Presence of calcitonin confers a diagnosis of small cell variant of MTC
 - Very aggressive-behaving tumor
- Prior to a diagnosis of a primary thyroid neuroendocrine carcinoma, a metastasis to thyroid gland from a neuroendocrine carcinoma of another organ (metastatic to or directly invading thyroid gland) site should be excluded.

THYROID PARAGANGLIOMA (Fig. 28-103)

Definition: Benign tumor originating from neural crest-derived paraganglia of autonomic nervous system identified in thyroid gland.

Clinical (Limited to the Thyroid Gland)

- Rare primary thyroid neoplasm
- More common in women than in men; occurs in adults
- Patients present with an asymptomatic thyroid mass; systemic symptoms are not present.
- Patients are euthyroid.
- Serum calcitonin levels not elevated
- Radioisotope scan shows presence of a hypofunctioning (“cold”) solitary mass
- Histogenesis:
 - Presence of intrathyroidal paraganglia has not been definitively identified.
 - Paraganglia, derived from inferior laryngeal paraganglial tissue, may be found in thyroid capsule,

Fig. 28-103. Thyroid paraganglioma.

A, Circumscribed tumor separated from thyroid parenchyma (*arrowheads*). **B**, Colloid-filled follicles (*arrowheads*) enveloped by tumor. **C**, Characteristic cell nest or organoid growth (Zellballen) separated by fibrovascular stroma and composed of cells with uniform nuclei and stippled-appearing nuclear chromatin. **D**, Lesional cells are diffusely and strongly reactive for synaptophysin. **E**, S100 protein preferentially is reactive in the peripherally located sustentacular cells although scattered tumor (chief) cells are also S100 protein positive.

perhaps migrating to this site during embryogenesis.

Pathology

Gross

- Encapsulated, firm lesions with a nodular appearance, tan-brown, and measuring up to 3.5 cm in greatest dimension.

Histology

- Histologic features include the presence of a cell nest or organoid growth (Zellballen) with a fibrovascular stroma that surrounds and separates tumor nests.
- Composed predominantly of chief cells, which are round or oval with uniform nuclei, dispersed chromatin pattern, and abundant eosinophilic, granular, or vacuolated cytoplasm:
 - Spindling of the chief cells may be present.
- Sustentacular cells represent other cellular component of tumor, which is difficult to appreciate by light microscopy:
 - These cells represent modified Schwann cells and are seen at the periphery of the cell nests as spindle-shaped, basophilic-appearing cells.
- No evidence of follicular differentiation or colloid formation within neoplasm
- Cellular pleomorphism may be seen; mitoses and necrosis are infrequently identified.
- Amyloid stroma not seen
- Histochemistry:
 - Tumor cells are argyrophilic (Churukian-Schenck).

- Reticulin staining delineates the cell nests.
- Argentaffin (Fontana-Masson), mucin, and periodic acid Schiff stains are negative.
- Immunohistochemistry:
 - Chief cells:
 - Reactivity for synaptophysin, chromogranin; S100 protein may be positive
 - Nonreactive for calcitonin, calcitonin gene-related protein (CGRP), CEA, thyroglobulin, TTF-1, cytokeratins
 - Sustentacular cells:
 - Reactivity for S100 protein, SOX10
- Electron microscopy:
 - Membrane-bound neurosecretory granules of varying sizes can be seen.
- Cytogenetics and molecular biology:
 - Mutations of PGL1 and SDH (succinate dehydrogenase) loci identified

Differential Diagnosis

- Hyalinizing trabecular tumor
- Medullary thyroid carcinoma
- Carotid body paraganglioma with extension into thyroid
- Papillary thyroid carcinoma

Treatment and Prognosis

- Conservative surgical excision (lobectomy) is curative.
- These tumors are benign:
 - Malignant behavior, as seen by locoregional invasion, is extraordinarily uncommon.
- Concomitant carotid body tumors may be present.

LYMPHOPROLIFERATIVE DISEASES OF THE THYROID GLAND

BENIGN LYMPHOPROLIFERATIVE DISORDERS

Langerhans Cell Histiocytosis (LCH) (Fig. 28-104)

Definition: Rare involvement of thyroid gland by Langerhans cell histiocytes.

Clinical and Pathology (Limited to Thyroid Involvement)

- For more complete discussion see Section 7, Ear and Temporal Bone.
- Thyroid involvement by LCH is rare and may occur:
 - Part of systemic disease with secondary thyroid involvement is more common:

- Patients present with thyroid nodule(s).
- Identified at autopsy
- As incidental microscopic foci identified in thyroid gland resected for other reasons (e.g., adenomatoid nodules, papillary thyroid carcinoma, lymphocytic thyroiditis, other) is less common
- No gender predilection; occurs over a wide age range from 2 months to 55 years, with a median age of 37 years
- Fine-needle aspiration biopsy:
 - Smears show isolated, loose aggregates and histiocyte-like cells with grooved or contorted nuclei mixed in varying proportions with many mature eosinophils, scattered and small lymphocytes, multinucleated giant cells, and foamy histiocytes.

Fig. 28-104. Langerhans cell histiocytosis of the thyroid.

A, Low magnification shows an incidentally identified small nodular-appearing focus in a background showing changes of chronic lymphocytic (Hashimoto) thyroiditis. **B**, At higher magnification, the cellular focus includes Langerhans cells characterized by vesicular nuclei with indented, notched, grooved, vesicular or “coffee-bean” shape and scattered eosinophils. Langerhans cells are immunoreactive for **(C)** S100 protein, **(D)** CD1a, and **(E)** Langerin.

- Histologically:
 - Thyroid involvement by LCH may be:
 - Focal (more common)
 - Diffuse
 - Langerhans histiocytes characterized by enlarged cells with vesicular nuclei and indented, notched, grooved, vesicular, or “coffee-bean”-shaped appearance, one or two nucleoli, and pale to eosinophilic finely vacuolated cytoplasm:
 - Intracytoplasmic phagocytosed cellular debris can be found.
 - Variable amount of eosinophils can be seen intermingled with the Langerhans cell histiocytes and tend to be more concentrated near areas of necrosis.
 - Histiocytic foci may infiltrate thyroid parenchyma, causing effacement of follicular architecture with destruction of thyroid follicles.
 - Reactive changes of follicular epithelium, including enlargement of cell size, can be seen.
 - Lymphocytic thyroiditis in the thyroid tissue not involved by LCH commonly found
 - Histiocytic cell proliferation may extend beyond the confines of the capsule, resulting in thyroid gland adhering to surrounding soft tissue or muscle.
 - Involvement of adjacent parathyroid gland(s) may occur.
- Immunohistochemistry:
 - Langerhans cells are reactive for:
 - S-100 protein, CD1a, Langerin
 - Lysozyme and CD68 also positive
 - No reactivity for thyroglobulin, TTF-1, cytokeratins
- Electron microscopy:
 - Intracytoplasmic rod-shaped granules (Birbeck granules) can be identified.

Treatment and Prognosis

- Localized disease treated by surgical resection
- Patients with isolated disease to thyroid, prognosis is favorable:
 - These patients do not subsequently develop systemic involvement.
- Systemic disease treated by combination chemotherapy
- Those patients with thyroid involvement associated with systemic disease have an aggressive clinical course with a poor prognosis.
 - Death due to disease-related complications generally occur in short periods of time (within 1 year).
- Given disparity in clinical outcome between localized (isolated) LCH versus systemic involvement, imperative to exclude systemic disease in those patients who may initially present with thyroid involvement

Extranodal Sinus Histiocytosis with Massive Lymphadenopathy (ESHML)

Definition: Idiopathic, predominantly nodal-based histiocytic proliferative disorder associated with an indolent biologic course with spontaneous resolution.

- Extranodal involvement may occur as part of a generalized process involving lymph nodes or may involve extranodal sites independent of lymph node status.

Synonyms: Rosai-Dorfman disease; Destombes-Rosai-Dorfman syndrome

Clinical and Pathology (Limited to Thyroid Involvement)

- For more complete discussion including images, see Section 1, Sinonasal Tract.
- Thyroid involvement by SHML is rare and may represent secondary extension from perithyroidal lymph nodes or may occur independent of nodal involvement.
- Clinically, SHML of thyroid may simulate subacute thyroiditis presenting with subclinical hypothyroidism and painful goitrous thyroid.
- Histology (cytopathology):
 - Histiocytic cells (so-called SHML cells), characterized by round to oval, vesicular to hyperchromatic nuclei, with an abundant amphophilic to eosinophilic, granular to foamy to clear-appearing cytoplasm; nucleoli may be prominent and eosinophilic or may be inconspicuous
 - Characteristically, SHML cells demonstrate emperipolesis:
 - Phagocytized cells most often lymphocytes but plasma cells, erythrocytes, and polymorphonuclear leukocytes can also be seen engulfed within the histiocytic cell cytoplasm.
 - Emperipolesis readily identifiable in nodal-based disease but extranodal sites may be more difficult feature to identify, although it can usually be found.
 - Can be diagnosed by fine-needle aspiration biopsy
- Immunohistochemistry:
 - SHML cells:
 - Most striking feature is presence of diffuse S100 protein reactivity but negative for CD1a and Langerin
 - Also demonstrate consistent immunoreactivity with vimentin, alpha-1-antichymotrypsin (ACT), CD68, lysozyme, and MAC-387
 - Less frequently, SHML cells may show immunoreactivity with Ki-1 and alpha-1-antitrypsin (AAT).

Fig. 28-105. DLBCL.

Diffuse large B-cell lymphoma of the thyroid gland, fine-needle aspiration biopsy. Cellular smear mostly composed of large lymphoid cells with nuclei over three times the size of admixed smaller lymphocytes (Diff-Quik).

- Negative for thyroglobulin, TTF-1, PAX8, calcitonin, neuroendocrine markers (e.g., synaptophysin, chromogranin)
- Too few cases of thyroid involvement to make any definitive comments on therapy and prognosis:
 - In all likelihood, treatment and behavior are similar to vast majority of patients with ESHML, who have an excellent prognosis, often with spontaneous resolution of their disease, without any specific therapy.

MALIGNANT LYMPHOPROLIFERATIVE NEOPLASM

Non-Hodgkin Malignant Lymphoma (NHML)

(Figs. 28-105 through 28-109)

Definition: Primary involvement of thyroid gland by malignant tumor composed of lymphoid cells usually of B-cells:

- Secondary involvement of thyroid gland by lymphoma more frequent than primary disease
- Approximately 20% of patients with disseminated lymphoma have thyroid involvement.
- For more complete discussion see Section 3, Pharynx.

Clinical

- Primary non-Hodgkin malignant lymphomas make up approximately 5% of all thyroid malignant

Fig. 28-106. DLBCL.

Primary thyroid malignant lymphoma with near complete replacement of the thyroid gland by a tan-white to yellow “fish flesh”-appearing lesion that on cut section has a bulging surface. Thyroid lymphomas tend to be poorly demarcated from the surrounding thyroid parenchyma and typically (completely) replace the involved thyroid tissue.

neoplasms and 2% to 3% of extranodal lymphomas.

- Much more common in women than in men; predominantly but not exclusively disease of older individuals in sixth to seventh decades of life
- Clinical presentation:
 - Usually rapidly enlarging, firm, and nontender thyroid gland:
 - Enlargement often occurs over a short period of time (weeks to months).
 - In general, only other thyroid neoplasm that presents as a rapidly enlarging thyroid mass is undifferentiated (anaplastic) thyroid carcinoma, which also tends to occur in the same age population as thyroid malignant lymphoma.
 - Other complaints may include:
 - Pain, hoarseness, dysphonia, vocal cord paralysis, dysphagia, dyspnea, and stridor
 - More uncommonly, superior vena cava obstruction may occur.
 - Not all thyroid lymphomas present as a rapidly enlarging mass; some may present as:
 - Gradual diffuse enlargement
 - Slowly growing nodule(s)
 - Development in patient with long-standing chronic lymphocytic (Hashimoto) thyroiditis
 - Incidental finding in thyroidectomy specimen:
 - Usually represents extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue, MALT type
- On palpation, thyroid gland is:
 - Usually asymmetric, hard, bulky mass often multinodular but may be uninodular

Fig. 28-107. Diffuse large B-cell lymphoma of the thyroid.

A, Cellular infiltrate with diffuse growth pattern and effacement of the thyroid parenchyma; residual adjacent thyroid parenchyma with changes of chronic lymphocytic (Hashimoto) thyroiditis is present (*lower right*). **B,** Sheets of large neoplastic cells infiltrate around residual thyroid follicles. **C,** Neoplastic cells colonize (pack or stuff) thyroid follicles creating lymphoepithelial lesions. **D,** Neoplastic lesional cells are round to oval nuclei with prominent eosinophilic nucleoli slightly larger than identifiable histiocytic nuclei (*arrowhead*) and at least twice the size of scattered small lymphocytes. The neoplastic cells are immunoreactive for **(E)** CD45 and **(F)** CD20.

Fig. 28-108. Extranodal marginal zone B-cell lymphoma of the MALT type of the thyroid gland.

A, In the lower portion of the illustration there is a diffuse cellular infiltrate with effacement of thyroid architecture and absence of identifiable germinal centers seen adjacent to residual thyroid parenchyma with changes of chronic lymphocytic (Hashimoto) thyroiditis (*upper left*), including an identifiable germinal center (*arrowhead*). **B**, In areas there is a vaguely nodular (follicular) pattern. **C**, Neoplastic infiltrate includes cells with dark staining and folded nuclei with scanty pale-appearing cytoplasm (centrocyte-like appearance). **D**, Lymphoepithelial cells characterized by neoplastic cells colonizing (packing or stuffing) thyroid follicles identified by the presence of residual follicular epithelial cells (*arrowheads*). **E**, Another example of a lymphoepithelial lesion in MALT lymphoma of the thyroid, including foci of necrosis and residual identifiable follicular epithelial cells (*arrowheads*).

Fig. 28-109. Extranodal marginal zone B-cell lymphoma of the MALT type of the thyroid gland.

A, Cells with plasmacytoid differentiation may be seen and may predominate in any given tumor, simulating a plasmacytoma. **B**, Crystalloid immunoglobulin deposits can be seen in the plasmacytoid cells. **C**, Neoplastic cells are immunoreactive for (*left*) CD45 and (*right*) CD20 that contrast to the findings seen in plasmacytomas that are CD45 negative and usually CD20 negative (as well as CD138 positive, not shown); in situ hybridization for immunoglobulin light chains show (**D**) kappa light chain restriction with (**E**) absence of lambda light chain.

- Cervical adenopathy (uni- or bilateral) may be present and includes varying degrees of nodal fixation.
 - Most patients are euthyroid.
 - Minority of patients may be hypothyroid probably caused by a pre-existing chronic lymphocytic (Hashimoto) thyroiditis rather than to lymphomatous infiltrate:
 - In setting of chronic lymphocytic (Hashimoto) thyroiditis, antithyroid antibodies (antithyroglobulin and antimicrosomal) may be present on laboratory analysis.
 - Rarely, hyperthyroidism may occur perhaps due to rapid destruction of thyroid follicular epithelium with release of colloid and thyroid hormone into circulation.
 - Radiology:
 - Appear as hypofunctioning “cold” nodules on thyroid scan:
 - Lymphomatous infiltrates do not concentrate radioiodine.
 - CT scans may show:
 - Nodularity
 - Extension or invasion within gland or into perithyroidal soft tissue
 - Necrosis and calcification
 - On ultrasound, thyroid lymphomas may appear as extremely hypoechoic masses.
 - Often this is in setting of a gland with decreased echogenicity due to presence of chronic lymphocytic (Hashimoto) thyroiditis.
 - Magnetic resonance imaging:
 - Shows an intensity similar to that of chronic lymphocytic (Hashimoto) thyroiditis
 - T2-weighted images show homogeneous areas of high intensity.
 - Etiology:
 - Chronic lymphocytic (Hashimoto) thyroiditis:
 - Thyroid lymphoma almost always associated with chronic lymphocytic (Hashimoto) thyroiditis:
 - Patients with chronic lymphocytic (Hashimoto) thyroiditis have an estimated 67 times greater risk than normal individuals of developing malignant lymphoma.
 - Factors supporting this relationship include:
 - Immunologically mediated (autoimmune) disease that may lead to development of malignant clone following persistent chronic antigenic stimulation of lymphocytes, thereby increasing susceptibility to neoplastic transformation
 - Transitional areas of reactive lymphoid hyperplasia to areas of unequivocal lymphoma can be seen.
 - Morphologic continuum exists between chronic lymphocytic (Hashimoto) thyroiditis and low-grade B-cell lymphoma and high-grade lymphoma.
 - Clonal rearrangements of immunoglobulin genes on rare occasion may be present in chronic lymphocytic (Hashimoto) thyroiditis.
 - Radiation:
 - Prior irradiation to head and neck region may represent another possible etiologic factor in development of thyroid malignant lymphoma.
 - Microorganisms:
 - Extranodal marginal zone lymphomas of mucosa-associated lymphoid tissue (MALT) are associated with various infectious pathogens
 - *Chlamydia psittaci* found in:
 - Nongastrointestinal MALT lymphomas, including thyroid MALT lymphoma
 - Autoimmune precursor lesions including but not limited to chronic lymphocytic (Hashimoto) thyroiditis by polymerase chain reaction amplification and direct sequencing
 - Suggests possible involvement of *C. psittaci*-induced antigenic-driven MALT lymphomagenesis
- Thyroid lymphomas share many features with lymphomas of salivary gland origin, including:
 - Both are associated with an immunologically mediated, extranodal lymphoid infiltrate:
 - Chronic lymphocytic thyroiditis for thyroid and lymphoepithelial sialadenitis (LESA) for salivary glands
 - Both show presence of lymphoepithelial lesions.
 - Both may present with lymphoma limited to particular site without concomitant or subsequent involvement of other sites.
 - Concomitant or metachronous involvement of other sites such as gastrointestinal tract may occur in thyroid and salivary gland lymphomas.

Pathology

- Virtually every type of non-Hodgkin malignant lymphoma occurs in thyroid gland:
 - Most are of B-cell immunophenotype.
 - Uncommonly, lymphomas with T-cell immunophenotype may occur.
- Nearly all thyroid lymphomas are either:
 - Diffuse large B-cell lymphoma (DLBCL): most common (>70%):
 - May arise de novo or via transformation of extranodal marginal zone B-cell lymphoma, MALT type
 - Extranodal marginal zone B-cell lymphoma (MALT lymphoma)

Fine-Needle Aspiration Biopsy

- DLBCL:
 - Cytologic diagnosis generally straightforward and not as problematic as diagnosis of MALT lymphoma
 - Cellular smear composed of monotonous and dis-cohesive population of large cells with round to oval, vesicular nuclei, prominent nucleoli, and moderate to abundant basophilic cytoplasm:
 - Twice as large as small mature lymphocytes
 - Numerous nuclei stripped of cytoplasm (“naked nuclei”)
 - Necrotic debris in the background
 - Lymphoglandular bodies (Söderström bodies, hyaline bodies, or lymphoid globules) may be identified:
 - Represent round (detached) cytoplasmic fragments of lymphoma cells with diameter between 2 and 7 μm
 - Appear pale basophilic in Romanowsky stained preparation
- MALT lymphoma:
 - Variable cellularity but usually cellular of lymphoid cells in isolation and in clusters
 - Heterogeneous cell population with admixture of small cells and intermediate sized (1.5 to 2 times as large as small mature lymphocytes) cells with slightly vesicular nuclei, pale chromatin, small nucleoli, and moderate amount of cytoplasm
 - Small cells may be admixed with larger cells with eccentric nuclei, coarse chromatin, and prominent nucleoli.
 - Plasmacytoid cells may predominate.
 - Numerous plasma cells may be present.
 - May be impossible to distinguish from Hashimoto thyroiditis

Gross

- Range in size from as small as 1 cm to >15 cm.
- On cut section, homogeneous, tan-white, “fish flesh” appearance, rubbery to hard consistency
 - Bulging surface
 - Necrosis may or may not be present.
- Poor demarcation from surrounding thyroid parenchyma may be present and complete replacement of thyroid gland may occur:
 - May involve one or both lobes
- Often extension beyond thyroid capsule into adjacent soft tissues:
 - Thyroid may be adherent to surrounding structures.
 - Hemorrhage and necrosis are usually not present.
- Non-neoplastic thyroid may be nodular or lobular in appearance with associated fibrosis.

- Suggest presence of chronic lymphocytic (Hashimoto) thyroiditis

Histology

General Features

- Following morphologic features seen in both DLBCL and MALT lymphoma:
 - Effacement of thyroid architecture
 - Neoplastic cellular infiltrate permeating between non-neoplastic follicles
 - Presence of lymphoepithelial lesions characterized by neoplastic cells “packing” or “stuffing” thyroid follicles:
 - In association with MALT lymphoma referred to as MALT balls
 - Absence of germinal centers within neoplastic infiltrate:
 - In lymphoma with a follicular growth pattern, follicles are composed of the neoplastic cellular infiltrate and do not demonstrate spectrum of differentiation normally seen in normal germinal center, including tingible body macrophages.
 - Extension of neoplastic infiltrate beyond thyroid capsule into perithyroidal soft tissues:
 - May result in thyroid being adherent to surrounding structures
 - Vascular invasion may be identified.

Diffuse Large B-Cell Lymphoma

(For more detailed discussion see Section 3, Pharynx.)

- Diffuse infiltrate comprised of sheets of large neoplastic cells with round to oval nuclei, vesicular chromatin, prominent eosinophilic nucleoli, and moderate amount of amphophilic cytoplasm:
 - Nuclear size \geq size of histiocyte nucleus and 2 \times size of small lymphocyte
- Immunohistochemistry (for more detailed discussion see Section, Pharynx):
 - CD45 positive
 - Reactivity for B-cell markers, including:
 - CD20, CD79a, PAX5
 - Cytokeratins, thyroglobulin, TTF-1, PAX8, calcitonin, and neuroendocrine markers negative:
 - Residual follicular epithelial cells reactive for cytokeratins, thyroglobulin, TTF-1, PAX8
- Cytogenetics and molecular genetics:
 - Occasional cases with:
 - t(8;14) involving *MYC* and immunoglobulin heavy chain (*IGH*)
 - Translocation of *BCL6* locus at chromosome 3q27
 - Thyroid carcinoma-associated genetic mutations reported, including:
 - *BRAF*, *NRAS*

Extranodal Marginal Zone B-Cell Lymphoma of the MALT Type

(For more detailed discussion, see Section 3, Pharynx.)

- Neoplastic cells:
 - Dark staining and folded nuclei with scanty pale-appearing cytoplasm (centrocyte-like appearance)
 - May colonize lymphoid follicles
 - Follicular colonization may be prominent, creating a follicular architecture simulating follicular lymphoma.
- Plasma cells commonly seen intermingled with neoplastic cells and may include:
 - Dutcher bodies
 - Cytoplasmic immunoglobulin invaginating into the nucleus creating the appearance of an intranuclear inclusion
 - Mott cells: Cytoplasmic immunoglobulin inclusion or crystals
- Plasmacytic differentiation may be seen and may predominate in any given tumor simulating a plasmacytoma:
 - In this setting, immunohistochemical stains are helpful in differentiating malignant lymphoma with plasmacytic differentiation from a plasmacytoma:
 - Malignant lymphoma with plasmacytic differentiation: CD45, CD20 positive
 - Plasmacytoma: CD45 negative; usually CD20 negative and CD138 positive
 - Monotypic immunoglobulin light chain restriction for either kappa or lambda light chain (by immunohistochemistry or in situ hybridization) may be present in approximately one third of cases.
- Large cell transformation of neoplastic cells may be present in areas adjacent to low-grade component and/or in follicles.
- Immunohistochemistry (for more detailed discussion see Section 3, Pharynx):
 - CD45, CD20, CD79a positive
 - CD5, CD10, CD23, BCL6 negative
 - Cytokeratins, thyroglobulin, TTF-1, PAX8, calcitonin, and neuroendocrine markers negative:
 - Residual follicular epithelial cells are reactive for cytokeratins, thyroglobulin, TTF-1, and PAX8.
- Cytogenetics and molecular genetics:
 - Clonal rearrangement of immunoglobulin heavy chain (*IGH*)
 - Chromosomal rearrangement t(3;14)(p14.1;q32) with *FOXP1/IGH* fusion found in approximately 50% of cases

Differential Diagnosis

- Chronic lymphocytic (Hashimoto) thyroiditis (Table 28-12)

- Undifferentiated (anaplastic) carcinoma
- Thyroid carcinoma with insular growth
- Medullary thyroid carcinoma

Treatment and Prognosis

- Prior to initiation of any therapy, clinical staging is essential for planning of treatment:
 - Clinical staging includes:
 - Radiologic assessment of neck, mediastinum, retroperitoneum, abdomen, and pelvis
 - Complete blood count
 - Bone marrow biopsy
 - Performed to exclude more widespread disease
- MALT lymphoma:
 - Almost always localized (stage I or II)
 - Early stage (stage IE) intrathyroidal MALT lymphomas typically have an indolent course and may be treated with single-modality surgery, radiotherapy, or a combination of both.
 - 62% 5-year survival for MALT lymphoma
 - Tumors with plasmacytic differentiation reported to have prognosis approaching 100% 5-year survival
- DLBCL:
 - More aggressive
 - More apt to have stage IIIIE or IVE disease
 - Survival outcomes highest with multimodal therapy incorporating monoclonal antibodies, chemotherapy, and radiotherapy
 - 45% 5-year survival rates for DLBCL
- Prognosis:
 - Prognosis in presence of extrathyroidal extension and/or higher-stage (widespread) disease significantly worse than low-stage disease:
 - With extrathyroidal extension 5-year survival is 35% to 40%.
 - With disseminated disease, 5-year survival is 5%.
- Need for thyroidectomy remains controversial:
 - Some surgeons advocate surgical resection of gland in patients with low-stage disease as it allows for removal of entire tumor.
 - Some surgeons advocate surgical excision of a sufficient amount of tissue for diagnostic purposes only, followed by initiation of radiotherapy and/or chemotherapy.
 - Surgical intervention justified for debulking of large tumors or decompression of tumors compromising vital structures
- Factors that affect prognosis include:
 - Stage:
 - Lower the stage, better the prognosis
 - Higher stage (with disseminated disease) 5% 5-year survival

TABLE 28-12 Thyroid Malignant Lymphoma versus Chronic Lymphocytic (Hashimoto) Thyroiditis

Features	Malignant Lymphoma	Chronic Lymphocytic (Hashimoto) Thyroiditis
Thyroid architecture and follicular epithelium	Effaced; destruction of follicular epithelium; lymphoepithelial lesions ("packing" or "stuffing" of the follicles with neoplastic cells)	Preserved; no destruction of follicular epithelium; oncocyctic cytoplasmic changes and nuclear enlargement; prominent nucleoli often seen; lymphoepithelial lesions not identified
Germinal centers	Absent in lymphomatous areas; follicles may be present but are composed of malignant cells without tingible body macrophages	May be rescent; heterogeneous cell population; tingible body macrophages in lymphoid follicles
Cellular components	DLBCL: Diffuse infiltrate comprised of sheets of large neoplastic cells with round to oval nuclei, vesicular chromatin, prominent eosinophilic nucleoli and moderate amount of amphophilic cytoplasm; MALT lymphoma: have dark staining and folded nuclei with scanty pale-appearing cytoplasm (centrocyte-like appearance) may colonize lymphoid follicles. Monotypic plasma cells may be intermingled with neoplastic cells.	Polymorphous composed of mature lymphocytes, histiocytes, and plasma cells
Extrathyroidal extension	Malignant cellular infiltrate often "spills out" into perithyroidal soft tissues; thyroid may be adherent to surrounding structures	Sharp outline between benign lymphocytic cell infiltrate and perithyroidal soft tissue; thyroid not adherent to surrounding structures
Immunohistochemistry	B-cell lineage specificity; show kappa or lambda light chain restriction	No lineage specificity or light chain restriction; both B-cells and T-cells are present in the benign cellular infiltrate; light chain restriction is not present
Associated parenchymal changes	Chronic lymphocytic thyroiditis	Squamous metaplasia; fibrosis; lymphoepithelial cysts

DLBCL, Diffuse large B-cell lymphoma; *MALT*, mucosa-associated lymphoid tissue.

- Extrathyroidal extension:
 - With extrathyroidal extension, 35% to 40% 5-year survival rate
 - For intrathyroidal tumors (without with extrathyroidal extension) >80% 5-year survival
- Cervical or mediastinal lymph node involvement associated with worse prognosis
- Age:
 - Patients over 65 years of age at diagnosis have worse prognosis.
- Tumor recurrence portends adverse prognosis.
- Other findings:
 - Large tumor size (>10 cm), presence of necrosis, and angioinvasion associated with worse prognosis

Other Thyroid Malignant Lymphoproliferative Neoplasms

- Thyroid involvement by other malignant lymphomas can occur but generally are uncommon and may include:
 - Follicular lymphoma:

- Rare
- Histologic features similar to follicular lymphoma of other sites
- May be associated with lymphoepithelial lesions
- Most cases associated with chronic lymphocytic (Hashimoto) thyroiditis
- Two groups based on clinical and pathologic findings:
 - First group (share features with nodal follicular lymphomas):
 - Histologic low-grade (grade 1-2/3)
 - Usually express CD10, BCL2 and/or have t(14;18)/IGH/BCL2 translocation
 - High clinical stage (III, IV)
 - Disease usually spread beyond thyroid involving lymph nodes and sometimes bone marrow
 - Achieve partial or complete remission after treatment
 - Second group:
 - Histologic high grade (grade 3/3)
 - Lack CD10, BCL2, and/or have t(14;18)/IGH/BCL2 translocation

- Low clinical stage (I)
 - Complete remission after treatment
- Plasmacytoma:
 - Rare
 - May be part of systemic multiorgan involvement (multiple myeloma) or occurs as an isolated phenomenon (extramedullary plasmacytoma)
 - Must be differentiated from extranodal marginal zone B-cell lymphoma of the MALT type with marked plasmacytic differentiation
 - For more complete discussion see Section 5, Larynx.
- Hodgkin lymphoma:
 - Rare in thyroid
 - Most often occurs secondary to cervical or mediastinal nodal disease
 - Rarely, may be primary in thyroid gland
 - Most common type is nodular sclerosing
- Rare thyroid lymphomas may include:
 - Burkitt lymphoma
 - Peripheral T-cell lymphoma, including anaplastic large cell lymphoma and some expressing $\gamma\delta$ T-cell receptor
 - Mantle cell lymphoma
 - Intravascular large B-cell lymphoma

NONEPITHELIAL NEOPLASMS OF THE THYROID EXCLUDING LYMPHOPROLIFERATIVE DISEASES

MESENCHYMAL TUMORS OF THE THYROID GLAND

Benign Mesenchymal Tumors

- Rare group of tumors that may occur in the thyroid gland
- May present as a solitary thyroid nodule or mass; may also be identified in thyroid gland removed for another lesion such as an adenomatoid nodule or a neoplasm (e.g., follicular adenoma)
- Neoplasms may include:
 - Vascular:
 - Hemangioma:
 - CD31, CD34, Factor VIII-related antigen reactivity
 - Lymphangioma
 - D2-40 (podoplanin) reactivity
 - Neural:
 - Benign peripheral nerve sheath tumor (benign Schwannoma)
 - Histology identical to soft tissue and other sites
 - Diffuse S100 protein and Sox10 (nuclear) reactivity
 - Negative for thyroglobulin, TTF-1, cytokeratins, calcitonin, neuroendocrine markers
 - Granular cell tumor:
 - Extraordinarily rare thyroid tumor
 - Histology identical to mucosal sites
 - Diffuse S100 protein reactivity as well as GFAP, CD68
 - Negative for thyroglobulin, TTF-1, cytokeratins, calcitonin, neuroendocrine markers
 - Muscle:
 - Leiomyoma (Fig. 28-110):
 - Encapsulated
 - Benign spindle cell proliferation lacking cytologic atypia, mitotic activity, or necrosis
 - Actin (muscle specific and smooth muscle actin) reactivity
 - Adipose tissue:
 - Lipoma and adenolipoma:
 - May in fact represent follicular epithelial cell neoplasm with associated mature fat rather than a true lipomatous neoplasm
 - Solitary fibrous tumor (SFT) (Fig. 28-111):
 - Rare thyroid tumor indistinguishable from pleural based on other extrapleural solitary fibrous tumors
 - Predominantly occurs in women; tumor of adult ages
 - Present as a slow-growing neck mass:
 - May occur in association with intrathoracic thyroid glands/goiters
 - Patients are euthyroid.
 - Grossly, well-circumscribed to encapsulated, solid, gray-white mass measuring from 2 to 8 cm; cystic foci may be seen
 - Morphologically identical to pleural and extrapleural counterparts, including:
 - Alternating hypercellular and hypocellular areas
 - Haphazardly arranged uniform, bland-appearing spindle- to stellate-shaped cellular proliferation with scanty cytoplasm and admixed collagen bundles (so-called ropey collagen)

Fig. 28-110. Intrathyroidal leiomyoma.

A, Intrathyroidal leiomyoma. Thinly encapsulated spindle cell tumor separated from adjacent thyroid parenchyma (*upper left*). **B**, At higher magnification the tumor is composed of bland cells with elongated, cigar-shaped nuclei. Immunoreactivity was present for smooth muscle actin (not shown).

Fig. 28-111. Solitary fibrous tumor of the thyroid gland.

A, Spindle cell proliferation merging with and enveloping thyroid follicles (*left*). **B**, Bland spindle- to stellate-shaped cells with indistinct cytoplasmic borders and stromal collagenization; lesional cells are immunoreactive for **(C)** CD34 and **(D)** STAT6 (nuclear).

- Absence of pleomorphism, mitotic activity, or necrosis
- Tend to have circumscribed borders but thyroid follicles may be entrapped at the periphery of the lesion
- Immunoreactivity present for:
 - CD34, STAT6 (nuclear), vimentin, bcl-2, and CD99
 - No immunoreactivity for cytokeratins, thyroglobulin, TTF-1, PAX8, calcitonin, neuroendocrine markers, S100 protein, SMA, desmin, CD5, and CD117
- Majority are benign but rare thyroid malignant SFTs reported characterized by:
 - Marked nuclear pleomorphism and increased mitotic activity
 - Local recurrence and pulmonary metastasis
- Surgical excision usually curative for thyroid benign mesenchymal neoplasms

Malignant Mesenchymal Tumors (Sarcomas)

General Considerations

- Primary sarcomas of thyroid gland are rare:
 - Prior to invoking a diagnosis of a primary thyroid sarcoma, involvement of thyroid secondary to a primary cervical neck or mediastinal sarcoma, or metastasis to thyroid from a remote site should be excluded.
- Thyroid sarcomas may include:
 - Angiosarcoma (see below)
 - Malignant peripheral nerve sheath tumor (malignant schwannoma)
 - Leiomyosarcoma (Fig. 28-112)
 - Liposarcoma
 - Fibrosarcoma
 - Osteosarcoma

Fig. 28-112. Thyroid leiomyosarcoma.

A, The tumor is unencapsulated and infiltrative comprised of spindle-shaped cells with fascicular growth. **B**, Neoplastic cells are pleomorphic with identifiable mitotic figures. Immunohistochemical confirmation of a leiomyosarcoma includes reactivity for **(C)** vimentin and **(D)** smooth muscle actin.

- Extrasosseous Ewing sarcoma family of tumors
 - Chondrosarcoma
 - Follicular dendritic cell tumor sarcoma (see Section 3, Pharynx, for more discussion)
- Whether these tumors are true sarcomas rather than undifferentiated (anaplastic) carcinomas with sarcomatoid features remains controversial issue:
 - Academic argument as treatment and prognosis generally follow that of an undifferentiated (anaplastic) thyroid carcinoma

Angiosarcoma (Figs. 28-113 and 28-114)

Definition: Malignant neoplasm with endothelial differentiation.

Synonyms: Epithelioid angiosarcoma; malignant hemangioendothelioma

- Controversial diagnosis:
 - Contention of those who do not believe thyroid angiosarcoma exists is that these are undifferentiated (anaplastic) thyroid carcinoma (UTC) with angiosarcomatous features.
 - Specific designation as angiosarcoma or as UTC with angiosarcomatous features appears moot because these are high-grade malignant neoplasms similarly treated and sharing same poor prognosis and outcome.

Clinical

- Extremely rare
- Demographics and clinical presentation similar to those of undifferentiated (anaplastic) thyroid carcinoma:
 - Tendency to occur in older individuals
 - More common in women than in men

Fig. 28-113. Thyroid angiosarcoma.

A, The tumor is composed of dilated, ramifying, and intercommunicating vascular spaces lined by malignant cells. **B,** Malignant cells lining the vascular-appearing channel include pleomorphic spindle-shaped nuclei with variably enlarged eosinophilic nucleoli. **C,** Rounded (epithelioid)-appearing nuclei with associated foamy histiocytes and a mitotic figure (arrow). **D,** Lesional cells are CD31 immunoreactive.

Fig. 28-114. Epithelioid angiosarcoma.

A, Malignant epithelioid neoplasm. **B**, Malignant cells are reactive for (left) cytokeratin (AE1/AE3) and (right) Factor VIII-related antigen. No immunoreactivity was present for thyroglobulin and TTF-1 (not shown).

- Clinical presentation:
 - Sudden enlargement of a long-standing goitrous thyroid with or without pain
 - May be associated with dyspnea and dysphagia
 - Chest pain and massive hemothorax may be present due to early metastatic tumor to the lung and pleura.
- Predilection for (but not exclusive to) mountainous or high-altitude regions of Europe (alpine regions):
 - Often iodine-deficient areas resulting in goitrous thyroids (endemic goiters)
 - Angiosarcomas often develop in long-standing goitrous glands.

Pathology

Fine-Needle Aspiration Biopsy

- Cellular smear composed of single cells and small clusters of neoplastic round to oval cells with eccentrically located nuclei, coarse nuclear chromatin, irregular nuclear membranes, single prominent

nucleoli vacuolated cytoplasm, and indistinct cell borders

- Features suggesting intracytoplasmic lumens may be identified.

Gross

- Typically large, invasive with associated necrosis and hemorrhage
 - Single nodule may be present.
 - Less commonly, may appear delineated or circumscribed nodular lesion

Histology

- Similar to high-grade (poorly differentiated) angiosarcomas of soft tissues characterized by:
 - Presence of dilated, ramifying, and anastomosing endothelial-lined vascular spaces
 - Presence of anastomosing vascular channels may only be focally present or obscured by solid cellular proliferation.
 - Endothelial cells are atypical or overtly malignant composed of spindle-shaped and epithelioid cells with large, pleomorphic, and vesicular nuclei, prominent nucleoli, and eosinophilic cytoplasm
 - Increased mitotic activity including atypical forms, hemorrhage, and necrosis consistently identified
 - Additional findings may include:
 - Vascular tufting
 - Intracytoplasmic vacuoles representing early attempts at lumina formation
 - Erythrocytes may or may not be present within these vacuoles
 - Multinucleated giant cells and bizarre cells can be seen.
- Invasive growth including destruction of thyroid follicular epithelium, as well as extrathyroidal extension often present
- Immunohistochemistry:
 - Endothelial markers including:
 - CD31, CD34, Factor VIII-related protein, Fli1 (nuclear), ERG (nuclear)
 - Vimentin positive
 - Cytokeratin usually negative:
 - May be positive (diffuse and strong intensity) especially in epithelioid angiosarcoma
 - Thyroglobulin, TTF-1, PAX8, calcitonin, neuroendocrine markers negative
- Electron microscopy:
 - Weibel-Palade bodies appearing as intracytoplasmic rod-shaped membrane-bound structures are specific for endothelial cells representing the storage site for Factor VIII-related protein; however, these are best identified in well-differentiated malignant vascular tumors and are very difficult

to identify in poorly differentiated vascular tumors.

- Other ultrastructural features that can be seen in endothelial neoplasms but that are not specific for endothelial neoplasms include pinocytic vesicles, basal lamina, cytoplasmic filaments, and intracytoplasmic vacuoles.

Differential Diagnosis

- Undifferentiated (anaplastic) thyroid carcinoma with angiosarcomatous features
- Carcinosarcoma or true malignant mixed tumors of thyroid gland:
 - Most probably represent undifferentiated (anaplastic) thyroid carcinoma with sarcomatoid differentiation rather than differentiation of a malignant tumor along epithelial and mesenchymal cell lines
- Post-fine-needle aspiration biopsy-induced changes in central portions of adenomatoid nodule that may include:
 - Dilated vascular channels with thrombosis and organization including interanastomosing channels
 - Papillary endothelial hyperplasia:
 - May occur spontaneously in association with other lesions (e.g., adenomatoid nodules) in absence of prior traumatic event such as a fine-needle aspiration biopsy

Treatment and Prognosis

- Combination surgery, radiotherapy, and chemotherapy
- Prognosis is dismal with median survival of less than 4 months from diagnosis.
- Highly aggressive with widespread local invasive growth and early dissemination to lungs, pleura, lymph nodes, bone, and adrenal glands
- Small tumors confined to thyroid gland without extrathyroidal extension may be associated with a more favorable prognosis.

Teratoma

Definition: True neoplasm composed of tissue types representing all three germ layers, including ectoderm, endoderm, and mesoderm, occurring in areas in which these tissues are not natively identified.

- Classification predicated on admixture of cell types and includes:
 - Mature teratoma
 - Immature teratoma
 - Malignant teratoma
- Histologic grading:
 - Determined on basis of extent of neuroectodermal tissue and includes:

- Grade 0 = completely mature (benign):
 - Immature tissue and/or neuroectodermal tissue absent
- Grade 1 = predominantly mature (benign):
 - Immature neuroectodermal tissue limited to rare foci not >1 low-power field per slide
- Grade 2 = predominantly mature (benign):
 - Immature neuroectodermal tissue common not >3 low-power field per slide
- Grade 3 = mostly immature (malignant):
 - Immature neuroectodermal tissue prominent >4 low-power field per slide
- Most common locations in head and neck include:
 - Neck and nasopharynx
 - Other less commonly involved sites include oral cavity (tonsil, tongue, palate), sinonasal cavity, external and middle ear and temporal bone, mandible and maxilla, and thyroid gland.

Thyroid Teratoma (Figs. 28-115 through 28-117)

- For teratoma of cervical neck to be considered of thyroid origin:
 - It must occupy a portion of the thyroid.
 - It must be in direct continuity or close anatomic relationship with the thyroid.
 - Is accompanied by total absence of thyroid gland
- Little clinical import ascribed to thyroid involvement by cervical teratoma in both adults and children; similarly, little clinical import relative to histogenesis (thyroid vs. nonthyroid) in those cervical teratomas that have anatomic relationship with thyroid gland

Fig. 28-115. Cervical/thyroid teratoma.

Infant with a massive midline and lateral teratoma that involved the thyroid gland.

Fig. 28-116. Cervical/thyroid teratoma.

Gross appearance of cervical/thyroid teratomas may include **(A)** solid and cystic with associated hemorrhage and **(B)** predominantly solid and focally cystic with a white appearance.

- Most thyroid teratomas occur in neonates and infants (pediatric teratomas).

Pediatric Thyroid Teratomas

- Most occur in stillborns, neonates, or infants <1 year old
- Present as large midline or lateral neck mass with or without airway compression and compromise
- Large, often measuring >10 cm in greatest dimension:
 - On cut section are solid to cystic in appearance
- Histologically, admixture of all three germ layers, including:

Fig. 28-117. Teratoma.

A, Intrathyroidal teratoma consisting of a respiratory epithelium (*lower left*), pancreatic tissue (*right*), and mature cartilage (*left of center*). **B**, *Left*, Intestinal-type mucin-producing epithelium (*top*) overlying neuroectodermal tissue including neurofibrillary matrix; *right*, mature cartilage and seromucous glands. **C**, Other example showing (*left*) ciliated respiratory and mucin-producing epithelium (*upper left*) and (*right*) primitive neuroectodermal tissue.

- Epithelial:
 - Keratinizing squamous, columnar, ciliated respiratory, or gastrointestinal-type epithelium, cutaneous adnexae, minor salivary glands
 - Thyroid follicular epithelium may be present (and should be confirmed as arising in thyroid) but may be extremely limited or absent.
- Neuroectodermal and central nervous system tissue that may include:
 - Mature glial tissue, neurofibrillary matrix, neural rosettes, choroid plexus, and/or pigmented retinal anlage
 - Immature neuroblastomal elements:
 - Diffuse or sheet-like growth
 - Small cells with hyperchromatic nuclei, increased nuclear-to-cytoplasmic ratio, increased mitotic activity, necrosis
 - Neural-type rosettes
 - Immunoreactivity may include NSE, GFAP, S100 protein, neurofilament protein
- Mesenchymal:
 - Cartilage, bone, fat, and muscle (smooth and skeletal)
- Surgical resection is preferred treatment.
- Most are benign with excellent prognosis:
 - Rarely, malignant teratomas occur in pediatric ages.
 - Thyroidectomy revealed no associated teratoma or other germ cell tumor.
 - Numerous bilateral pulmonary nodules present but no evidence of mediastinal mass
 - Favorable response to bleomycin, etoposide, and cisplatin chemotherapy
- Mixed germ cell tumor, including:
 - Embryonal carcinoma and choriocarcinoma
 - Occurred in 35-year-old man
 - Associated with high serum concentration of beta-HCG
 - Orchiectomy negative for tumor.

THYROID LESIONS WITH THYMIC DIFFERENTIATION

Spindle Epithelial Tumor with Thymus-Like Differentiation (SETTLE) (Figs. 28-118 and 28-119)

Definition: Low-grade malignant thyroid tumor characterized by lobulated architecture and presence of spindle-shaped epithelial cells and glandular-appearing structures.

Synonyms: Intrathyroid spindle cell tumor with mucous cysts; thyroid thymoma

Clinical

- Rare thyroid tumor
- Slight male predominance; may occur over a wide age range (first to eighth decades) but tends to occur most often in first and second decades of life with a mean age at diagnosis of 13½ years
- Clinical presentation usually that of asymptomatic (painless) thyroid or neck mass:
 - Less often patients may present with tenderness, tracheal compression, enlarging neck mass, or diffuse enlargement of thyroid gland.
 - Infrequently, regional nodal metastasis may be identified at presentation.
- Patients are euthyroid.
- Radiologic imaging:
 - “Cold” thyroid nodule
- Histogenesis:
 - Possible origin from remnants of branchial pouch
 - No definitive evidence to support thymic derivation

Pathology

Gross

- Vary from encapsulated to partially encapsulated to circumscribed to infiltrative
- Solid, tan-white, and firm, measuring from 1.8 to 5 cm in greatest dimension

Adult Thyroid Teratomas

- More common in women than in men; occurs over a wide age range, including children and young adults
- Often malignant akin to immature teratomas of gonads
- Histology:
 - Usually grade 3 (malignant):
 - Prominent neuroectodermal component (immature neuroblastomal elements)
 - May include yolk sac or embryonal components
- Treatment includes surgery, radiation, and chemotherapy.
- Most are malignant with aggressive behavior:
 - Invasive growth into adjacent structures
 - Tend to recur and metastasize (regional lymph nodes, distant)
 - Usually fatal over short time periods irrespective of attempts at controlling disease, including total thyroidectomy, radiation, chemotherapy
- Rare cases of primary thyroid extragonadal:
 - Yolk sac tumor:
 - Occurred in 10-year-old girl
 - Associated with marked elevation of serum α -fetoprotein levels

Fig. 28-118. SETTLE.

Spindle cell tumor with thymus-like differentiation (SETTLE). **A**, Sclerotic stroma divides tumor into incomplete lobules composed of a biphasic tumor, including spindle-shaped cells with reticulated pattern and glandular structures, the latter including mucinous cells. **B**, Spindle-shaped cells are characterized elongated hyperchromatic nuclei with little cytoplasm and minimal nuclear pleomorphism merging with a glandular structure lined by respiratory and mucin-producing epithelium.

- Vague whorled appearance and cysts may be present.

Histology

- Cellular neoplasm composed of spindle-shaped cells blending imperceptibly with epithelial structures (biphasic pattern):
 - Presence of sclerotic stroma dividing tumor into incomplete lobules
 - Spindled zones blend imperceptibly into areas showing epithelial differentiation.
 - Spindle-shaped cells:
 - Fascicular, reticular, and hyalinized growth patterns
 - Sharp interface with stroma
 - Elongated nuclei with delicate chromatin and inconspicuous nucleoli and little cytoplasm

- Minimal pleomorphism and mitotic activity
- Epithelial structures:
 - Appear in form of tubules, papillae, cords, glomeruloid glandular structures, Sertoli-like tubules, small glands, epithelial lined cystic spaces, and small islands
 - Lined by cuboidal to columnar cells with round or plump-appearing cells with round to oval, bland nuclei and moderate amount of cytoplasm
 - Branching or cystic glands lined by mucinous or respiratory epithelium containing abundant intracytoplasmic mucin may focally be present.
 - Squamous metaplasia may rarely be present.
- Entrapped thyroid follicles can be seen.
- An inflammatory cell component is typically scanty.
- Other uncommon findings:
 - Monophasic variant exclusively composed of either spindle-shaped cells or glandular structures may occasionally occur.
 - Mitoses and necrosis are typically absent, but an occasional case may have increased mitotic activity and necrosis.
 - Invasive growth including vascular space invasion can be identified.
- Histochemistry:
 - Mucin-positive material can be found along the luminal surface of the glandular spaces.
- Immunohistochemistry (all lesional cells):
 - Cytokeratins:
 - Extensive expression of AE1/AE3, CAM 5.2
 - Widespread CK7 expression
 - Limited expression of low-molecular-weight cytokeratins and EMA
 - CK20 negative
 - Vimentin, CD99, bcl-2, CD117, and INI-1 seen in majority of cases
 - p63 (nuclear) appears to be restricted to spindle-shaped cells, whereas glandular structures are nonreactive
 - TLE1 expression in rare cases
 - Thyroglobulin, TTF-1, PAX8, calcitonin, CEA, synaptophysin, chromogranin, S100 protein, and CD5 negative
- Electron microscopy:
 - Spindle cells show tonofilaments, desmosomes, and basal lamina.
- Cytogenetics and molecular genetics:
 - Absence of *SYT/SSX* translocation

Differential Diagnosis

- Synovial sarcoma:
 - Presence of t(X;18) translocation with *SYT/SSX* gene fusion may assist in the differential diagnosis from SETTLE.

Fig. 28-119. SETTLE.

Another example of spindle cell tumor with thymus-like differentiation (SETTLE). **A**, Variably sized cellular nodules separated by sclerotic stroma. **B**, Biphasic tumor including spindle-shaped cells with fascicular growth pattern blending imperceptibly with glandular structures (*arrows*). **C**, The spindle-shaped cells include elongated nuclei with hyperchromatic to vesicular nuclei and minimal nuclear pleomorphism merging while the glandular structures form tubules and are lined by cuboidal to plump-appearing cells with round to oval, bland nuclei. **D**, Both glandular structures and spindle cells are cytokeratin (CAM 5.2) reactive. **E**, p63 (nuclear) expression preferentially marks spindle-shaped cells but not glandular structures.

- Ectopic thymoma:
 - Only rarely occurs in thyroid gland
 - Strong female predilection; most occur in middle age
 - Noninvasive
 - Histologically identical to mediastinal thymoma:
 - Encapsulated to circumscribed with jigsaw puzzle–like configuration
 - Admixture of epithelial cells (polygonal to spindle-shaped) and small lymphocytes
 - Prominent T-cell-rich infiltrate (TdT-positive)
- Thyroid (immature) teratoma
- Undifferentiated (anaplastic) thyroid carcinoma
- Spindle cell (sarcomatoid) squamous cell carcinoma

Treatment and Prognosis

- Surgical excision is preferred treatment:
 - May include lobectomy, subtotal thyroidectomy, or total thyroidectomy
- Variable and unpredictable behavior that includes:
 - Benign course
 - Protracted clinical course with development of delayed distant metastasis to (in descending order):
 - Lungs, cervical lymph nodes, mediastinum, kidney, and soft tissues
 - Overall metastatic rate of 71% with more than 5 years of follow-up
 - Despite metastatic disease clinical course may be protracted prior to death due to disease
 - 90% 5-year survival rate

Carcinoma Showing Thymus-Like Differentiation (CASTLE) (Fig. 28-120)

Definition: Thyroid gland carcinoma with features of thymic epithelial tumors.

Synonyms: Intrathyroidal epithelial thymoma; primary thyroid thymoma; lymphoepithelioma of thyroid gland; lymphoepithelioma-like carcinoma of thyroid

Clinical

- Rare tumor
- More common in women than in men; occurs over a wide age range with a mean age of 48½ years at diagnosis
- Clinical presentation usually that of asymptomatic thyroid or neck mass:
 - Most occur in thyroid gland (lower poles)
 - May arise in perithyroidal soft tissues
 - May be invasive at presentation with extension into adjacent soft tissue structures or fixation to or invasion of the trachea, resulting in symptoms related to tracheal compression or even hoarseness

- Patients are euthyroid.
- Radiologic imaging:
 - “Cold” thyroid nodule
- Histogenesis:
 - Probably originates from intrathyroidal thymic remnants
 - Origin from solid cell nests suggested may arise from branchial pouch remnants, the thyroid SCNs.

Pathology

Gross

- Vary from encapsulated to circumscribed to invasive
- Firm to hard in consistency, gray to pink, measuring from 3.5 to 5.8 cm in greatest dimension

Histology

- Architecture resemblance to lobulated appearance seen in thymic tumors (thymoma or thymic carcinoma), including:
 - Solid nests or lobules with an expansile or infiltrative growth into thyroid tissue in broad fronts
 - Dense fibrous bands and/or delicate fibrovascular stroma separate lobules and create lobulated or septated appearance
 - Limited to dense inflammatory component including lymphocytes and plasma cells identified
- Cellular composition includes epithelioid cells with large, pleomorphic nuclei with vesicular chromatin, small distinct nucleoli, and abundant eosinophilic cytoplasm with indistinct cell borders:
 - Squamous differentiation may be present, including:
 - Keratinization and intercellular bridges
 - Foci of abrupt keratinization resembling Hassall corpuscle may be present
 - Spindle-shaped tumor cells may be present.
- Mitotic activity can be seen:
 - 1 to 2 mitoses per 10 high-power fields
- Scanty to heavy inflammatory cell infiltrate may be seen in association with the epithelial cells.
- Ectopic thymic tissue may be identified in vicinity of tumor.
- Immunohistochemistry:
 - Tumor cells:
 - Cytokeratins and p63 positive
 - CD5 and CD117 almost always positive
 - Thyroglobulin, TTF-1, PAX8, calcitonin, and neuroendocrine markers negative:
 - Rarely, synaptophysin and chromogranin reactivity reported
 - EBV (by immunohistochemistry and in situ hybridization [EBER]) negative
 - p16 negative

Fig. 28-120. Carcinoma showing thymus-like differentiation (CASTLE).

A, The tumor is demarcated from thyroid parenchyma (*right*) composed of cords and trabecular and solid nests separated by fibrous stroma. **B**, Cords/trabeculae separated by fibrous stroma. **C**, Syncytial-appearing cells with indistinct cell borders, vesicular nuclei, and prominent nucleoli; a sparse inflammatory cell infiltrate. **D**, In this example a more prominent associated inflammatory cell infiltrate is present, in part obscuring the neoplastic cells. **E**, Limited foci with squamous differentiation including associated keratinization may be seen. The neoplastic cells are immunoreactive for **(F)** CD5 (membranous),

**Fig. 28-120, cont'd**

(G) cytokeratin (AE1/AE3), and (H) CD117.

- Lymphocytes:
 - Express markers of both T- and B-cells
- Electron microscopy:
 - Desmosomes, tonofilaments, and elongated cell processes can be seen.

Differential Diagnosis

- Undifferentiated (anaplastic) thyroid carcinoma:
 - PAX8 positive
 - CD5, bcl-2, and CD117 negative
- Metastatic undifferentiated carcinoma (e.g., from Waldeyer tonsillar ring or oropharynx):
 - Nasopharyngeal undifferentiated carcinoma: EBER positive
 - Oropharyngeal undifferentiated carcinoma: p16 positive
 - CD5, bcl-2, and CD117 negative.
- Squamous cell carcinoma
- Follicular dendritic cell sarcoma

Treatment and Prognosis

- Surgical resection with or without radiotherapy is preferred treatment:
 - Lobectomy or subtotal thyroidectomy
 - Neck dissection indicated in the presence of clinically and/or radiographically suspicious or positive cervical lymph node metastasis
- Postoperative radiotherapy is recommended owing to:
 - Considered to be radiosensitive tumors
 - Prognosis generally good
 - Pursue an indolent course.
 - Local recurrence is common.
 - Local recurrence and regional nodal metastasis may occur years following resection.

- Often successfully controlled by surgery or radiotherapy
- 5- and 10-year cause-specific survival rates 90% and 82%, respectively
- Nodal metastasis and tumor extension predict worse prognosis.
- Death attributable to aggressive course with massive local disease or lung metastasis may rarely occur.

SECONDARY OR METASTATIC TUMORS TO THE THYROID (Figs. 28-121 through 28-123 and Box 28-8)

- Thyroid gland may be secondarily involved by malignant tumors originating from other sites:
 - May take the form of direct invasion from a malignant neoplasm of a nearby site or via hematogenous spread from a distant primary malignant tumor
- Among tumors that invade directly into thyroid from an adjacent organ are mucosal tumors of the larynx, pharynx, trachea, and esophagus.
 - By far, squamous cell carcinoma (or one of its histologic variants) is most common type of malignant tumor that invades directly into the thyroid gland.
- Metastatic tumors to thyroid from distant primary site can occur from virtually every organ system (Table 28-13):
 - Most frequent tumors to metastasize to thyroid gland include (in descending order):
 - Renal cell carcinoma (34%)
 - Lung carcinoma (15%)
 - Breast carcinoma (14%)

- Gastrointestinal carcinoma (14%)
- Malignant melanoma (5%)
- Others
- Metastatic tumors to thyroid gland may occur from an occult primary source and simulate appearance of a primary thyroid tumor.

Fig. 28-121. Metastatic renal cell carcinoma, FNAB.

Metastatic renal cell carcinoma to thyroid, fine-needle aspiration biopsy (FNAB) is characterized by cells with clear-appearing cytoplasm, distinct cell borders, vesicular nuclei, and inconspicuous to small nucleoli (Papanicolaou). These features could be those of a primary thyroid clear cell neoplasm. In the presence of such findings clinical history of a renal cell carcinoma would certainly support a diagnosis of a metastasis, but if material is available immunohistochemical staining would be invaluable in determining if the lesion is primary to the thyroid or possibly represents a metastasis.

- Thyroid involvement by metastatic deposits from distant sites most often seen in autopsy material
- Clinically detectable thyroid mass due to metastatic disease occurs in a minority of patients:
 - In patients with a clinically detectable mass, metastatic tumor to the thyroid presents as a rapidly growing thyroid mass of recent onset.
 - Patients are generally euthyroid, although some patients may present with disturbances in thyroid function (hyperthyroidism).
- Radiology:
 - May appear as a single hypofunctioning (“cold”) mass on thyroid scan and as solid and/or cystic lesions on ultrasonography

BOX 28-8 Secondary or Metastatic Tumors to the Thyroid Gland

Epithelial

- Kidney, breast, lung, gastrointestinal, hepatobiliary and pancreas, genitourinary tract, others

Melanocytic/Neuroendocrine

- Malignant melanoma
- Neuroendocrine carcinomas (especially small cell carcinoma)

Hematolymphoid

- Non-Hodgkin malignant lymphoma
- Hodgkin disease
- Leukemia
- Others

Mesenchymal

- Kaposi sarcoma
- Others

Fig. 28-122. Metastatic renal cell carcinoma to the thyroid gland.

A, A cellular proliferation composed of clear-appearing cells is located within adenomatoid nodule (*lower left*). **B**, Nests and lobules of tumor separated by fibrovascular stroma.

Fig. 28-122, cont'd

C, Instead of colloid, often the central aspect of a metastatic renal cell carcinoma contains red blood cells. This is a helpful but not diagnostic feature seen in renal cell carcinomas and generally not in primary thyroid tumors. **D**, Lesional cells are characterized by clear-appearing cytoplasm with small, round, hyperchromatic nuclei and sharply delineated cell borders. Immunohistochemical staining includes reactivity for **(E)** CD10 (membranous), **(F)** renal cell carcinoma (RCC) antibody, **(G)** PAX2 (nuclear), and **(H)** carbonic anhydrase IX.

Fig. 28-123. Metastatic lobular carcinoma of the breast to the thyroid gland.

A, At low magnification a circumscribed thyroid lesion composed of follicles with oncocytic cells (*arrows*) as well as an apparent second cellular component composed of darker-appearing nuclei (*arrowhead*). **B** and **C**, Admixture of cells with brightly eosinophilic cytoplasm (follicular cells) as well as cells with signet ring cell appearance containing intraluminal mucinous-appearing material (metastatic lobular carcinoma). Immunohistochemical staining shows **(D)** thyroglobulin restricted to follicular epithelial cells, **(E)** TTF-1 restricted to follicular epithelial cells, and **(F)** mammaglobin restricted to metastatic lobular carcinoma. The findings are those of breast lobular carcinoma metastatic to a follicular adenoma, oncocytic type, a finding that may be referred to as “tumor within tumor” or “tumor-to-tumor” metastasis.

TABLE 28-13 Follicular Tumors with Clear Cells versus Metastatic Renal Cell Carcinoma

Features	Follicular Adenoma/Carcinoma with Clear Cells	Metastatic Renal Cell Carcinoma
Luminal secretion	Colloid; will be PAS positive	No colloid; red blood cells; pseudofollicles
Nested growth with fibrovascular stroma	Present	Present
Cytoplasm	Foamy appearing	Clear with distinct cell borders
Nuclear	Round; dispersed or coarse chromatin	Small, round, hyperchromatic
Glycogen (diastase-sensitive, PAS-positive)	Yes, but colloid will be diastase-resistant	Yes; intensely positive
IHC findings	Thyroglobulin, TTF-1, PAX8 positive CD10, RCC, CAIX, PAX2 negative	Thyroglobulin, TTF-1 negative CD10, RCC, CAIX, PAX2, PAX8 positive

CAIX, Carbonic anhydrase IX; IHC, immunohistochemistry; RCC, renal cell carcinoma antibody; TTF-1, thyroid transcription factor 1.

- Metastatic deposits may simulate appearance of primary thyroid lesion.
- Multiple lesions may be more indicative of metastatic tumor.
- Histology:
 - Metastasis often occurs to pre- or coexisting primary thyroid lesion:
 - Primary thyroid lesions may include:
 - Adenomatoid nodule
 - Thyroid neoplasm (follicular adenoma, follicular carcinoma, papillary carcinoma, medullary carcinoma)
 - Possible clue is presence of thyroid lesion with contrasting morphologies
 - May be referred to as “tumor within tumor” or “tumor-to-tumor” metastasis
 - Renal cell carcinoma may present most difficult metastatic tumor to differentiate from a primary clear cell neoplasm of the thyroid gland (Table 28-13):
- Immunohistochemical staining should allow for confirmation of metastatic tumor and differentiation from primary thyroid neoplasm:
 - Renal cell carcinoma:
 - CD10, renal cell carcinoma (RCC) antibody, PAX2, PAX8, carbonic anhydrase IX positive
 - Thyroglobulin, TTF-1, calcitonin, neuroendocrine markers negative
 - Lung adenocarcinoma:
 - Napsin A, TTF-1 positive
 - Thyroglobulin, TTF-1, calcitonin, neuroendocrine markers negative
 - Breast (mammary duct) carcinoma:
 - Mammaglobin, BRST2, e-cadherin positive
 - Thyroglobulin, TTF-1, PAX8, calcitonin, neuroendocrine markers negative
 - Breast (lobular) carcinoma:
 - Mammaglobin, BRST2 positive
 - e-cadherin negative
 - Thyroglobulin, TTF-1, PAX8, calcitonin, neuroendocrine markers negative
 - Gastrointestinal carcinoma:
 - CK20, CDX2 (nuclear), villin positive
 - Thyroglobulin, TTF-1, PAX8, calcitonin negative
 - Malignant melanoma:
 - S100 protein, HMB-45, melan-A, tyrosinase, MITF1, Sox10 (nuclear), and vimentin positive
 - Thyroglobulin, TTF-1, PAX8, calcitonin, neuroendocrine markers negative
- Treatment and prognosis:
 - Surgical resection of a metastatic tumor may inadvertently occur when metastatic tumor presents as a metastasis from an occult primary neoplasm.
 - Surgical resection is an acceptable treatment modality even for some tumors that are known to be metastatic to the thyroid (i.e., renal cell carcinoma).
 - External irradiation and chemotherapy may be used in treatment.
 - Despite attempts at controlling disease, prognosis in patients with metastatic tumor to thyroid is generally poor:
 - Death usually occurs within 2 years after identification of metastasis to thyroid
 - Cause of death usually due to widespread metastatic disease from respective primary tumor
 - Exceptionally prolonged survival following surgical resection (lobectomy or total thyroidectomy) may occur in renal cell carcinoma in which metastatic disease is limited to the thyroid gland.

Thyroid Gland Post Fine Needle Aspiration Biopsy (FNAB)-Related Histologic Changes and Intraoperative Consultation

POST FINE NEEDLE ASPIRATION BIOPSY (FNAB)-RELATED MORPHOLOGIC CHANGES (Figs. 29-1 through 29-11)

- FNAB has tremendous utility as first interventional diagnostic procedure relative to a patient with a thyroid mass.
- Diagnostic sensitivity and specificity of FNAB of a thyroid mass is high.
- In many situations, surgical removal is treatment for a thyroid mass lesion irrespective of diagnosis by FNAB.
- FNAB may result in a number of histologic changes in resected thyroid gland that may create diagnostic challenges:
 - Histologic alterations caused by FNAB may lead to an erroneous diagnosis, such as changing interpretation from a benign process to a malignant one.
 - Pathologists must be aware of diversity of changes that may occur induced by FNAB.
- Post-FNAB histologic changes occur in numerous lesions, including adenomatoid nodules, hyperplastic lesions, follicular adenoma and its variants, follicular carcinoma and its variants, and papillary carcinoma and its variants.
- Oncocytic (oxyphilic) cells may be present in a wide variety of thyroid lesions (e.g., adenomatoid nodules, follicular adenoma, follicular carcinoma, papillary carcinoma, others) and are more prone to retrogressive changes secondary to a traumatic event such as FNAB owing to prominence of oxygen-sensitive mitochondria in these cells:
 - Any compromise to oxygen supply of oncocytic cells may result in retrogressive changes, including:
 - Cyst formation, papillary architecture, hemorrhage, infarction
- Based on type of reaction seen post-FNAB alterations may include acute or chronic changes:
 - Acute changes usually identified within 3 weeks from FNAB to surgical removal and may include:
 - Hemorrhage with hemosiderin-laden macrophages and granulation tissue:
 - Represent most common findings:
 - Localized follicular destruction
 - Capsular alterations
 - Atypical cytologic features with necrosis and mitoses:
 - Nuclear atypia is reactive or reparative, typically occurs near the needle tract, and includes nuclear enlargement (nucleomegaly), hyperchromasia, prominent nucleoli
 - Chronic changes usually identified more than 3 weeks from FNAB to surgical removal and may include (individually or in combination):
 - Metaplasia:
 - Squamous or oncocytic cells
 - Mucous cell may uncommonly be identified.
 - Infarction
 - Nuclear atypia, including nucleomegaly, hyperchromasia, and prominent nucleoli
 - Cyst formation
 - Papillary architecture
 - Fibrosis
 - Calcifications
 - Hemorrhage (recent and remote in form of hemosiderin-laden macrophages) and/or cholesterol granuloma formation
 - Capsular alterations with pseudoinvasive growth and/or epithelial displacement:
 - May take the form of a needle tract in which there is a linear-appearing “bud” into fibrous capsule
 - ◻ Low magnification appearance suggests capsular invasion, but at higher magnification follicular epithelium does not violate capsule.
 - ◻ Rather, needle tract composed of dense fibrosis as well as chronic inflammatory cells infiltrate including macrophages and giant cells with or without hemorrhage

Fig. 29-1. Post-FNAB changes.

Post-FNAB hemorrhage and infarction of a follicular adenoma, oncocytic type.

Fig. 29-2. Post-FNAB changes.

A, Post-FNAB changes in this follicular adenoma, oncocytic type, include cystic degeneration, papillary architecture, and fresh hemorrhage. **B**, At higher magnification the follicular cells (*right*) show the presence of granular, brightly eosinophilic cytoplasmic changes (so-called Hürthle cells) with associated hemorrhage and infarction (*left*).

Fig. 29-3. Post-FNAB infarction of a papillary carcinoma.

- (recent and remote, latter in form of hemosiderin deposition); cholesterol granuloma formation may be present.
 - Epithelial displacement
- Vascular alterations, including:
 - Dilated vascular spaces with thrombosis, organization, papillary endothelial hyperplasia (Masson tumor-like reaction), and endothelial cell atypia:
 - May suggest presence of a vascular tumor such as hemangioma or even an angiosarcoma
 - Temporal sequence from the FNAB to surgical removal is an important factor in the interpretation of these findings.
 - Artfactual implantation or “invasion” of tumor cells within endothelial-lined space:
 - In this setting, cells float within vascular lumens and are not adherent to vessel wall and/or have associated fibrin thrombus formation as seen in true vascular invasion.
- Reparative changes may be exuberant, including spindle-shaped cells (fibroblasts) that may simulate a sarcoma and have been referred to as post-FNAB spindle cell nodule.
- Needle tract tumor implantation:
 - Rare occurrence
 - Reported in association with papillary thyroid carcinoma
 - Intervals between FNAB and detection of implantation range from 2 to 131 months
 - Location of carcinoma cells in line of needle insertion include:

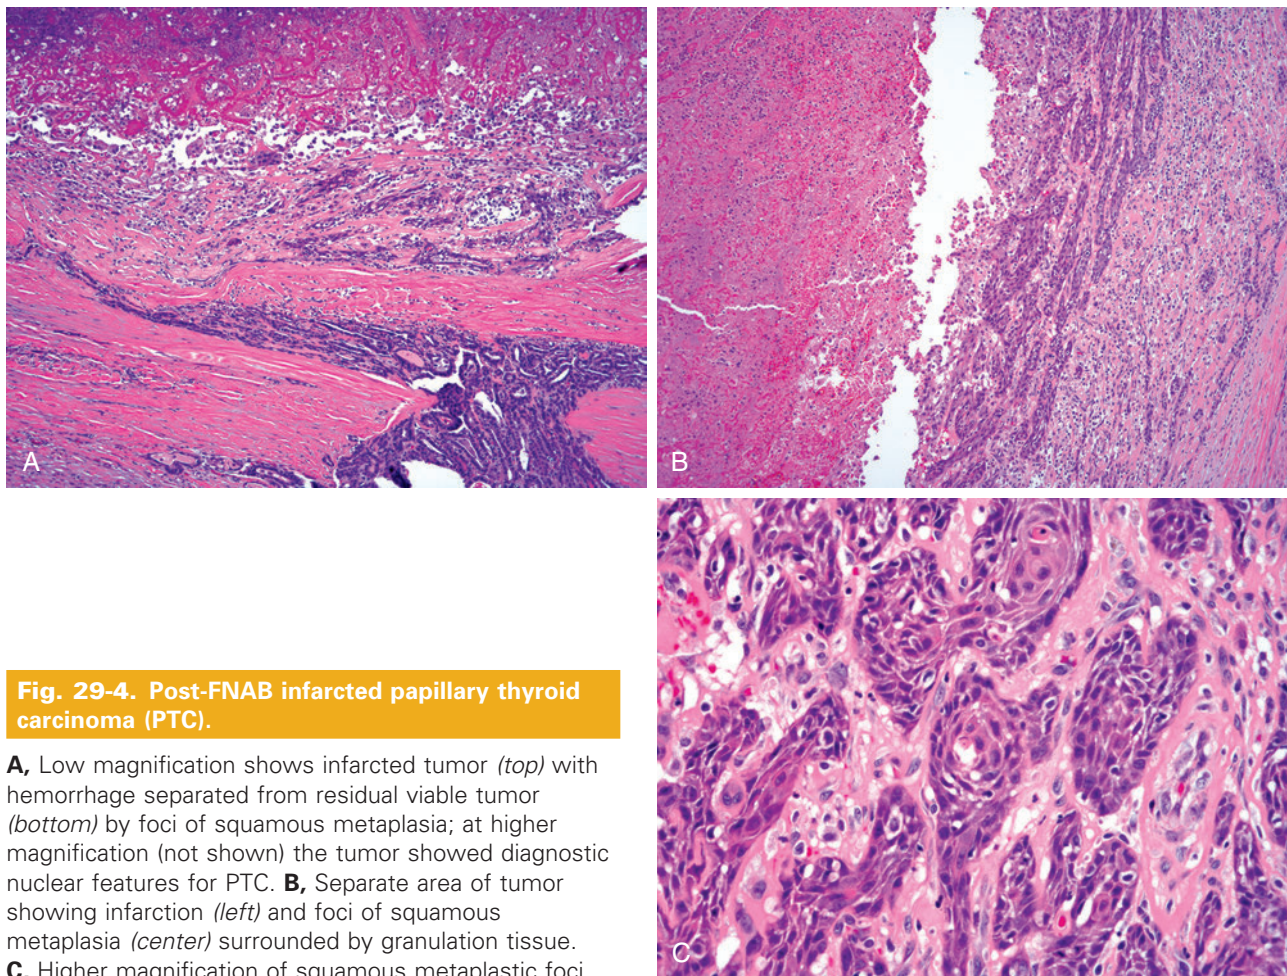

Fig. 29-4. Post-FNAB infarcted papillary thyroid carcinoma (PTC).

A, Low magnification shows infarcted tumor (*top*) with hemorrhage separated from residual viable tumor (*bottom*) by foci of squamous metaplasia; at higher magnification (not shown) the tumor showed diagnostic nuclear features for PTC. **B**, Separate area of tumor showing infarction (*left*) and foci of squamous metaplasia (*center*) surrounded by granulation tissue. **C**, Higher magnification of squamous metaplastic foci.

Fig. 29-5. Needle tract and capsular pseudoinvasion.

Left, The appearance at low magnification includes linear-appearing "bud" into fibrous capsule, suggesting capsular invasion. *Right*, At higher magnification, the needle tract bud includes mixed inflammatory cells and hemorrhage.

- Subcutis
- Within strap muscles
- None of the lesions included lymph node components on pathology.
- Implanted tumors surgically removed without recurrence at focal sites

INTRAOPERATIVE CONSULTATION (IOC) (FROZEN SECTION) OF THE THYROID GLAND

(Figs. 29-12 through 29-20)

Indications

- Most effective in cases in which fine-needle aspiration biopsy (FNAB) results are suspicious for malignancy (Bethesda V)
- Render a histologic diagnosis.
- Differentiate a benign lesion (e.g., adenomatoid nodule[s], adenoma) from a malignant neoplasm that may require additional surgery (i.e., total or near total thyroidectomy).

Fig. 29-6. Needle tract with epithelial displacement.

A, B, Follicular epithelial cells (*arrowheads*) displaced along needle tract that includes chronic inflammatory cells, hemorrhage, fibrosis, and foreign body giant cell reaction; follicular epithelium does not violate the capsule.

- Identification of nonsentinel nodal metastasis:
 - Role of sentinel lymph node sampling not established for thyroid tumors
- Incisional biopsy with intraoperative consultation (IOC) may occur:
 - In patients with unresectable disease (e.g., undifferentiated [anaplastic] carcinoma)
 - To ensure adequacy for diagnosis in certain clinical settings (e.g., unresectable disease) or in relationship to certain tumor types (e.g., hematolymphoid tumors)

Surgeon's Expectations

- Establish a correct diagnosis.
- Differentiate a benign (non-neoplastic or benign tumor) from a malignant tumor.

Fig. 29-7. Post-FNAB changes.

Post-FNAB changes in adenomatoid nodule: **(A)** infarction (*upper right*), fibrosis, chronic inflammation, squamous metaplasia, and calcifications; **(B)** granulation tissue and cholesterol granuloma formation.

- Identification of nodal metastasis in cases in which lymph nodes are resected and sent for IOC
- Identify additional findings that may affect treatment.

Specimen Handling

- Lobectomy specimen:
 - Ink exterior of specimen.
 - Serially sectioned in “breadloaf” manner
 - Cut section through center of lesion and measure it.
 - Section to include capsule-to-tumor interface.
 - Weigh gland (optional).
- Subtotal or total thyroidectomy specimen:
 - If removed with preoperative diagnosis of malignancy (e.g., by FNAB):
 - Ink exterior of specimen.
 - Gross examination usually suffices.
 - Weigh gland (optional).

Fig. 29-8. Post-FNAB vascular changes.

Post-FNAB vascular alterations may include **(A and B)** blood-filled spaces simulating the appearance of a hemangioma; **(C through E)** vascular proliferation adjacent to area of infarction simulating an angiosarcoma, including **(C)** dilated, ramifying, and interconnecting channels, **(D)** nuclear atypia, and **(E)** mitotic figures (*arrowhead*).

Fig. 29-9. Papillary endothelial hyperplasia.

A, B, Post-FNAB vascular alterations may include papillary endothelial hyperplasia characterized by the presence of numerous papillae projecting into vascular lumens composed of a single layer of endothelium surrounding a collagenized core.

Fig. 29-10. Pseudovascular invasion.

A, Post-FNAB of a follicular adenoma showing artifactual implantation of tumor cells within an intracapsular endothelial-lined vascular space (*arrow*). **B,** At higher magnification, the tumor cells are free floating, the blood vessel lacking adherence to the vessel wall and/or associated fibrin thrombus formation as would be seen in bona fide vascular invasion.

- Follicular adenoma versus follicular carcinoma:
 - Recommendation is that at least four blocks from tumor-to-capsule-to-thyroid interface be examined, but the number of sections is not considered “standard of practice” and number of blocks examined is a decision made by individual pathologist.

Gross Findings

- Observation of macroscopic features important to proper evaluation and sectioning in thyroid resections include:
 - Number of lesions/nodules identified
 - Circumscription/encapsulation versus poorly circumscribed versus invasive
 - Presence of intralesional fibrosis:
 - Often seen in papillary thyroid carcinoma but not a pathognomonic finding
 - Presence of retrogressive changes including cyst formation, hemorrhage, calcifications:
 - Often seen in association with adenomatoid nodule(s)
 - Color:
 - Brown to red color indicative of oncocytic cells

Fig. 29-11. Post-FNAB spindle cell nodule in an adenomatoid nodule.

A and B, Low magnification shows fascicular to storiform growth with scattered mitotic figures (*arrowhead*).
C and D, Spindle-shaped to epithelioid-appearing fibroblasts with enlarged nuclei, prominent nucleoli, and mitotic figure (*arrowhead*).

- Glistening appearance suggests prominence of colloid as may be seen in adenomatoid nodules or follicular adenoma.

Intraoperative Cytology

- Cytologic preparations (touch preps, scrap preps, needle aspiration):
 - Should be performed in all cases as considered essential in IOC of thyroid lesions:
 - May provide cytomorphologic features less well observed on frozen section preparation
 - Used in conjunction with frozen sections as complimentary diagnostic tool
 - Increases diagnostic accuracy

Diagnostic Considerations

See [Table 29-1](#) for diagnostic categories.

- Papillary thyroid carcinoma (PTC)
- Follicular adenoma
- Follicular carcinoma
- Adenomatoid nodules
- Chronic lymphocytic (Hashimoto) thyroiditis
- Medullary thyroid carcinoma (MTC)
- Post-fine-needle aspiration biopsy changes (see first section in this chapter):
 - Cyst formation
 - Fibrosis
 - Hemorrhage

Text continued on p. 1467

Fig. 29-12. Intraoperative consultation, papillary thyroid carcinoma usual type.

A, Low magnification shows a follicular epithelial lesion with papillary architecture. **B**, Areas showing elongated and irregular-appearing follicles and intratumoral fibrosis. **C**, Papillae, elongated follicles, and intratumoral fibrosis. **D** and **E**, At higher magnification diagnostic nuclear including nuclear enlargement, variation in nuclear size and shape, crowding, overlapping, and intranuclear inclusion (*arrow*); note absence of optically clear nuclei, which is an artifact of fixation and not a feature seen on frozen section.

Fig. 29-13. Intraoperative consultation, papillary thyroid carcinoma (PTC), follicular variant.

A, Encapsulated follicular epithelial tumor without invasive growth that is entirely composed of follicular architecture without evidence of papillae. **B**, Areas showed nuclear features suggestive of papillary thyroid carcinoma. **C**, Other areas show the presence of intranuclear inclusions that in conjunction with other nuclear features supports the diagnosis of papillary thyroid carcinoma. **D** and **E**, Cytologic (touch) preparations show unequivocal diagnostic features for PTC, including enlarged nuclei with variation in size and shape, dispersed (very fine)-appearing nuclear chromatin, nuclear grooves, and intranuclear inclusions (*arrows*).

Fig. 29-14. Intraoperative consultation, follicular adenoma.

A, Encapsulated follicular epithelial tumor with no evidence of invasion. **B**, Cytomorphology includes rather uniform-appearing cells with round nuclei and coarse nuclear chromatin lacking nuclear features diagnostic for papillary thyroid carcinoma.

Fig. 29-15. Intraoperative consultation, follicular carcinoma minimally invasive.

A and **B**, Low magnification showing tumor invading into and through its capsule but at the time of IOC definitive evidence of angioinvasion was not identified. **C** and **D**, On permanent section evidence of angioinvasion in the form of tumor within capsular endothelial-lined vascular spaces was seen and confirmed the diagnosis of (minimally invasive) follicular carcinoma.

Fig. 29-16. Intraoperative consultation, follicular carcinoma.

A, In this image separate foci of tumor are seen protruding into and through the capsule. **B,** Other areas show mushroom-like protrusion of the tumor completely bifurcating the capsule. **C and D,** Permanent sections confirm the capsular invasion as evidenced by the presence of "mushroom-like" growth through the capsule.

Fig. 29-17. Intraoperative consultation, capsular pseudoinvasion in a follicular adenoma.

A, B, Not infrequently limited protrusion of tumor into the capsule may be seen but the extent of protrusion does not qualify as capsular invasion; angioinvasion was not present.

Fig. 29-18. Intraoperative consultation, adenomatoid nodules.

A and B, This lesion was part of multiple nodules that were circumscribed but not encapsulated and composed of colloid-filled follicles with bland nuclear morphology. **C and D,** Retrogressive changes in adenomatoid nodules may include cyst formation and papillary architecture, but there was an absence of nuclear findings associated with papillary thyroid carcinoma (on frozen section and touch preparation, not shown). **E and F,** Cellular adenomatoid nodule—despite the increase cellularity there is an absence of invasion and an absence of nuclear findings associated with papillary thyroid carcinoma (on frozen section and touch preparation, not shown).

Fig. 29-19. Intraoperative consultation, chronic lymphocytic (Hashimoto) thyroiditis.

A, Thyroid gland characterized by multiple nodules separated by fibrous tissue and associated dense lymphoid infiltrate. **B,** At higher magnification the thyroid follicular cells with oncocytic cytoplasm changes and associated dense lymphocytic cell infiltrate.

Fig. 29-20. Intraoperative consultation, medullary thyroid carcinoma.

A, Circumscribed cellular tumor lacking evidence of colloid formation demarcated from the adjacent normal thyroid parenchyma (*top*). **B** and **C,** Areas of the tumor show acellular extracellular eosinophilic material that proved to be amyloid. **D,** At higher magnification the tumor cells are composed of variably pleomorphic round nuclei with dispersed nuclear chromatin. Touch preparations at the time of frozen section assist in the diagnosis, showing

**Fig. 29-20, cont'd**

(**E**) nuclear characteristics of medullary thyroid carcinoma including round cells, some with a plasmacytoid appearance, with dispersed nuclear chromatin, (**F**) scattered multinucleated giant cells, and (**G**) extracellular amyloid material.

TABLE 29-1 Intraoperative Consultation: Diagnostic Categories

Lesion	Diagnostic Consideration
Follicular lesion low cellularity/large follicles	Adenomatoid nodules Follicular adenoma
Encapsulated cellular follicular lesion with no invasion	Follicular neoplasm, defer PTC Follicular neoplasm suspicious for malignancy
Follicular lesion with invasion	Follicular carcinoma; PTC, follicular variant
Invasive papillary lesion	PTC and variants
Other	Medullary carcinoma, lymphoma, anaplastic carcinoma

PTC, Papillary thyroid carcinoma.

- Infarction
- Nuclear atypia
- Vascular alterations
- Capsular pseudoinvasion
- Vascular pseudoinvasion

Diagnostic Accuracy of IOC of the Thyroid Gland

- 98% correlation between IOC, including FS and cytologic preparation, and final histologic diagnosis
- Average deferral rate of 11% (compared with average deferral rate of 3% for other sites)
- Reoperation rate 1.4%

Contraindications and Limitations of IOC of Thyroid Gland Lesions

- Not indicated in cases diagnosed as definitive for malignancy (Bethesda VI), including:
 - Papillary thyroid carcinoma
 - Poorly differentiated thyroid carcinoma
 - Medullary thyroid carcinoma
 - Undifferentiated (anaplastic) carcinoma
 - Squamous cell carcinoma
 - Metastatic carcinoma
 - Malignant lymphoma
 - In such cases the preoperative surgical plan includes total thyroidectomy, in which there is no information generated by IOC that would alter surgical approach.
 - Exception to this scenario would be evaluation of lymph nodes for nodal metastasis that may prompt neck dissection at time of IOC.
- Limited to no utility in cases in which FNAB diagnosis is “follicular lesion of undetermined significance” or “follicular neoplasm or suspicious for follicular neoplasm” (Bethesda IV), including those lesions with oncocytic (so-called Hürthle) cells:
 - In many of these cases differential diagnosis primarily includes follicular adenoma versus follicular carcinoma, in which differentiating criteria (i.e., invasive growth) may:
 - Be only focally identified and not readily observed at time of IOC

- Require numerous sections more appropriately performed on permanent section evaluation and not in frozen sections

- Diagnosis of follicular carcinoma:
 - Problematic issue given the fact majority of follicular carcinomas are low grade and may show only focal/limited evidence of capsular invasion and/or angioinvasion on permanent section
 - Guidelines include at least four sections be taken from the tumor-to-capsule-to-stromal interface, but foci of invasion may not be evident even in multiple sections.

SUMMARY

- IOC of thyroid gland lesions is most effective where FNAB is suspicious for but not definitively diagnostic of carcinoma.
- Not indicated in cases diagnosed as definitive for malignancy by FNAB
- Is at best of limited value and arguably of no value in the diagnosis of minimally invasive (low-grade) follicular carcinoma

Embryology, Anatomy, and Histology of the Parathyroid Glands

EMBRYOLOGY

- Parathyroid glands are of endodermal origin and originate as symmetric, nodular epithelial proliferations on the dorsal aspects of the third and fourth pharyngeal pouches around the fifth week of gestation.
- Superior gland develops from the fourth pharyngeal pouch, which is connected with the pharynx, from which it separates. The fourth pharyngeal pouch is a complex bilobed structure composed of a ventral component; the ultimobranchial body, which fuses with the lateral aspect of the thyroid lobe; and a dorsal epithelial proliferation, which separates to become the superior thyroid gland, assuming the usual adult position along the posteromedial aspect of the thyroid gland. The superior parathyroid glands tend to be more constant in position than the inferior glands.
- Inferior parathyroid glands develop from the third pharyngeal pouch, also a complex bilobed structure, associated with the thymus, from which it separates after migrating caudally to a position near the lower pole of the thyroid gland.
- Most common “anomaly” of the parathyroid glands is ectopia, which usually represents a variation in embryologic migratory pattern.

- Parathyroid agenesis is very rare:
 - DiGeorge syndrome includes:
 - Complete or partial absence of the third and fourth pharyngeal pouches and their derivatives: the thymus, the parathyroid glands, and the C cells
 - Disease is manifested by multiple facial malformations, hypoplasia of the thyroid, hypoparathyroidism, and cardiac abnormalities.

ANATOMIC CONSIDERATIONS

(Fig. 30-1)

- Most individuals have at least four parathyroid glands; approximately 13% of the population has supernumerary glands, ranging in number from one additional gland to as many as 12 glands in rare instances.
- Rare individuals with fewer than four glands have been reported; however, there is doubt in at least some of the cases that all of the glands were identified.
- Supernumerary glands may be well formed (about half of the cases) or may be less distinct aggregates of parathyroid tissue located near the normal glands.

Fig. 30-1. Anatomy of the parathyroid glands.

(From Miller FR, Netterville JL: *Surgical management of thyroid and parathyroid disorders*, Med Clin North Am 83(1):247, 1999, Fig. 1.)

- There is considerable variation in the location of the parathyroid glands in adults, though their distribution follows a predictable pattern based on their embryologic development.
- The superior glands are more constantly placed than the lower glands:
 - The superior glands are located along the posterior edge of the thyroid superior to the intersection between the recurrent laryngeal nerve and the inferior thyroid artery (approximately 80%).
 - 20% are found posterior to the upper pole of the thyroid, where they may be intimately associated with the thyroid capsule
 - The superior glands may rarely be retroesophageal or retropharyngeal, or even intrathyroidal.
- The lower glands are more variably placed:
 - Although the most common location is around the posterolateral or inferior aspects of the lower pole of the thyroid gland (approximately 60%), they may be found within the portion of the thymus that is adjacent to the lower pole of the thyroid.
 - Because the inferior glands pursue a lengthy developmental migratory course, they may be found from the level of the hyoid bone to the mediastinum, where they may be situated in thymic tissue or in the pericardium.

BLOOD SUPPLY AND LYMPHATICS

- Arteries and veins:
 - Blood supply is from the superior and inferior thyroid arteries or from anastomoses between the superior and inferior thyroid arteries.
 - If glands are ectopic in location, the arterial supply may be from the esophageal or pharyngeal arteries.
 - Venous drainage:
 - Upper glands via superior or lateral thyroid vein
 - Lower glands via lateral or inferior thyroid vein
- Lymphatics:
 - Originates from subcapsular plexus into the superior deep cervical, pretracheal, paratracheal, retropharyngeal, and inferior deep cervical lymph nodes

INNERVATION

- Derived from the sympathetic ganglia (superior or middle cervical ganglia) either directly or indirectly through a plexus in the fascia of the posterior surface of the thyroid lobes:
 - Nerves are probably vasomotor rather than secretomotor.

HISTOLOGY (Figs. 30-2 through 30-4; Table 30-1)

- Parathyroid glands are soft yellow-brown to dark brown, circumscribed ovoid structures; some parathyroid glands are bilobed or flattened.
- Normal size and weight (see Table 30-1):
 - Each gland measures approximately 3 to 6 mm in length.
 - Combined weight increases from early infancy (mean, 5 to 9 mg) to the third or fourth decade (mean for males, 120 mg; for females, 142 mg).
 - The actual parenchymal cell mass represents about 74% of the weight of adult parathyroid glands.
- Capsule of the parathyroid glands consists of delicate fibrous tissue.
- Within the glands there is an arborizing meshwork of arterioles, venules, and a myriad of capillaries that give the glands an extremely rich blood supply.
- Parathyroid glands in infants and children:
 - Very cellular, with little stromal collagen and very few stromal fat cells
 - Number of stromal fat cells begins to increase around puberty and continues to increase until the third to fifth decades.
 - Stromal fat is variable in its distribution among individuals as well as within a single gland, making the relative percentage of stromal fat a tenuous feature in evaluation of parathyroid proliferations.
 - Chief cells arranged in solid sheets with minimal intervening stroma
 - Oncocytic (oxyphilic) and transitional oncocytic cells are not normally observed.
 - Chief cells are small and have faintly eosinophilic cytoplasm with less intracellular fat than the cells of adult parathyroid glands.
 - More variable architectural features appear, beginning in puberty with the accumulation of more stromal tissue.
- Adult parathyroid glands:
 - Composed predominantly of chief cells (although they are larger and contain more intracytoplasmic fat than the chief cells in children):
 - Nuclei are round and tend to be rather hyperchromatic due to a coarse chromatin pattern typical of neuroendocrine cells.
 - Cytoplasm is amphophilic or slightly eosinophilic to somewhat clear.
 - Parenchymal cells of adult parathyroid glands are arranged in solid groups, cords, nests, and follicle-like structures, with intervening stromal tissue:

Fig. 30-2. Normal parathyroid gland.

A, Normal parathyroid gland in an adult composed of chief cells and abundant intraparenchymal mature fat. **B**, Solid groups of chief cells that have small hyperchromatic, round nuclei and clear appearing cytoplasm. The chief cells stain for **(C)** parathyroid hormone, **(D)** parafibromin (nuclear staining), and **(E)** chromogranin.

Fig. 30-3. Normal parathyroid gland.

A and B, The normal parathyroid gland may include a follicular growth pattern with central colloid-like material simulating the appearance of thyroid follicles. **C,** The eosinophilic colloid-like material is PAS-positive. Parathyroid gland origin is confirmed by immunohistochemical staining for **(D)** parathyroid hormone and **(E)** parafibromin (nuclear staining) but is negative for thyroglobulin and TTF1 (not shown).

Fig. 30-4. Normal parathyroid gland.

The normal parathyroid gland in adults may include oncocytic cells (**A**) interspersed with the chief cells as a nodular focus. Note the presence of abundant intraparenchymal mature fat. **B**, At higher magnification the oncocytic cells are characterized by brightly eosinophilic-appearing cytoplasm. Oncocytic cells are immunoreactive for (**C**) parathyroid hormone (PTH) and (**D**) chromogranin but the staining for these markers tends to be less intense as compared with PTH and chromogranin staining in association with chief cells.

TABLE 30-1 Comparison of Normal Parathyroid Tissue to Abnormal Parathyroid Tissue

Parameter	Normal Range	Abnormal Changes
Number	Usually 4, sometimes 5	Ectopia
Size	Length 3-6 mm Width 2-4 mm Thickness 0.5-2.0 mm	Enlarged gland greater than 6 mm
Weight	Approx. 30 mg each: men: 120 ± 3.5 mg women 142 ± 5.2 mg	Any gland weighing greater than 60 mg
Percentage fat	Approximately 17%, rarely more than 50%; more in women than in men	Complete absence or very few intraparenchymal fat cells
Intracytoplasmic lipid	Abundant	Absent or scanty

Modified from Chan JKC: The parathyroid gland. In Fletcher CDM: Diagnostic histopathology of tumors, ed 4, Philadelphia, 2013, Elsevier Saunders, p 1274.

- Follicle-like structures often contain eosinophilic PAS positive material that resembles colloid:
 - Colloid-like material is not immunoreactive for thyroglobulin or thyroid transcription factor 1 (TTF1).
 - Resemblance of this colloid-like substance to amyloid at a light microscopic and ultrastructural level has been noted.
- Prominent lipid droplets are present in 70% to 80% of the chief cells.
- Chief cells, which are “active” in the secretory process, contain little or no cytoplasmic lipid; they also contain more secretory granules as evidenced by silver stains or by chromogranin staining.
- Women generally have a higher percentage of stromal fat than men.
- Generally stromal fat represents about 50% of total stromal volume.
- Stromal fat content is affected by several variables, including nutrition, body habitus, general state of health, and heredity.
- Immunohistochemical staining in normal parathyroid gland chief cells includes:
 - Parathyroid hormone (PTH), parafibromin (nuclear stain), chromogranin A, cytokeratins (CK8, CK18, CK19), and CD4
 - No reactivity for thyroglobulin, TTF1, PAX8, and calcitonin
 - Cyclin D1 present in approximately 6% of cases
- Oncocytic cells and transitional oncocytic cells are also found in the adult parathyroid:
 - Oncocytic cells are larger than chief cells and have striking eosinophilic granular cytoplasm.
 - Ultrastructural studies indicate that the cytoplasmic granularity results from the enormous number of mitochondria in these cells.
 - Nuclei of oncocytic cells are usually pyknotic.
 - Immunoreactivity includes:
 - Parathyroid hormone (PTH) and chromogranin A but less intense staining as compared to chief cells; chromogranin may be negative.
 - Parafibromin (nuclear stain)
 - Cytokeratins (CK8, CK18, CK19) are positive although less intense as compared to chief cells.
 - No reactivity for thyroglobulin, TTF1, PAX8, CD4, and calcitonin
 - Oncocytic cells may be interspersed in small groups among the chief cells, or they may form nodules.
 - Relative number of oncocytic cells and the tendency to form oncocytic cell nodules increase with age.
 - In older individuals oncocytic nodules (single, multiple) are common.
 - Transitional oncocytic cells appear to represent an intermediate phase in the transition from chief cells to oncocytic cells.
 - Although the oncocytic cells in normal glands do not seem to be actively secreting parathyroid hormone, hyperfunctioning oncocytic neoplasms have been reported.

Parathyroid Glands: General Considerations

HYPERPARATHYROIDISM

Definition: Hyperparathyroidism is the state of elevated serum parathyroid hormone (PTH) as a result of excessive secretion (overproduction).

- Hyperparathyroidism is the most common pathologic condition affecting the parathyroid glands.
- Causes of hyperparathyroidism due to parathyroid-related disorders are listed in [Box 31-1](#).
- Parathyroid-independent hypercalcemic disorders are listed in [Box 31-2](#).
- Hyperparathyroidism is divided into primary, secondary, and tertiary categories.
- Reference range for intact PTH in normal adults is 10-65 pg/ml.

Primary Hyperparathyroidism

Definition: Inappropriately elevated PTH secretion due to intrinsic abnormality of parathyroid gland(s), in the

BOX 31-1 Causes of Hyperparathyroidism Due to Parathyroid-Related Disorders

Primary

- Parathyroid proliferative disease, including:
 - Adenoma (approximately 85% of cases)
 - Hyperplasia (approximately 13% of cases)
 - Carcinoma (approximately 2% of cases)
- Syndromes associated with hyperparathyroidism include (see Section 10 for more complete discussion):
 - Multiple endocrine neoplasia (MEN)-1
 - MEN-2A
 - Hyperparathyroidism-Jaw syndrome
 - Less common syndromes associated with hyperparathyroidism include:
 - Familial hypocalciuric hypercalcemia
 - Familial hypercalcemic hypercalciuria
 - Neonatal severe primary hyperparathyroidism
 - Familial isolated hyperparathyroidism
- Rarely may be associated with parathyroid cyst

Secondary

- Chronic renal failure (most common)
- Dietary vitamin D deficiency or abnormalities of vitamin D metabolism
- Malabsorption
- Pseudohypoparathyroidism

Tertiary

- Same as secondary hyperparathyroidism

absence of known stimulus for PTH secretion causing elevation of serum calcium (hypercalcemia) with decreased serum phosphate (hypophosphatemia); hypercalciuria is common.

Clinical

- Current reported annual incidence is 0.04 per 1000 persons.
- Causes for primary hyperparathyroidism include the group of lesions collectively referred to as *parathyroid proliferative disease* composed of ([Fig. 31-1](#)):
 - Parathyroid adenoma: approximately 85% of cases
 - Parathyroid hyperplasia: approximately 13% of cases
 - Parathyroid carcinoma: approximately 2% of cases
- Syndromes associated with hyperparathyroidism include (see Section 10 for more complete discussion):
 - Multiple endocrine neoplasia (MEN)-1
 - MEN-2A
 - Hyperparathyroidism-Jaw syndrome
 - Less common syndromes associated with hyperparathyroidism include:
 - Familial hypocalciuric hypercalcemia
 - Familial hypercalcemic hypercalciuria
 - Neonatal severe primary hyperparathyroidism
 - Familial isolated hyperparathyroidism
- Rarely, primary hyperparathyroidism is associated with parathyroid cyst.

BOX 31-2 Parathyroid-Independent Hypercalcemia

- Hypercalcemia of malignancy
- Vitamin D intoxication
- Granulomatous diseases
 - Sarcoidosis
 - Other
- Hyperthyroidism
- Vitamin A intoxication
- Adrenal insufficiency
- Thiazide diuretics
- Milk-alkali syndrome
- Renal failure
- Immobilization
- Other

Fig. 31-1. Normal parathyroid glands and parathyroid gland abnormalities.

Drawings of the normal-appearing parathyroid glands and the appearance of the major causes of hyperparathyroidism.

(Modified from www.netterimages.com. From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 41-93, p 2661.)

- More common in women than in men; primarily occurs in middle and older ages with a mean age of occurrence in the sixth decade of life; may occur over a wide age range from the second to ninth decades of life.
- Symptoms are related to the level and duration of serum calcium elevation:
 - Patients are commonly asymptomatic or present with vague complaints, such as lethargy, weakness, polyuria, polydipsia, arthralgia, constipation, and depression.
 - Rather nonspecific presentation has been encountered more often in the past two decades when routine biochemical testing has resulted in an overall increase in the prevalence of primary hyperparathyroidism by detection of clinically silent cases.
- “Classical” primary hyperparathyroidism was characterized by:
 - Advanced bone disease: *osteitis fibrosa cystica* with increase of osteoclastic bone resorption accompanied by fibrovascular marrow replacement and increased osteoblastic activity:
 - Radiographic evidence of general demineralization of bone
 - Subperiosteal resorption most evident in the phalanges of the hands
 - Bone cysts, often multiple, with a tendency to occur in central medullary portions of the metacarpals, ribs, and pelvis
 - Osteoclastomas or “brown tumors” found in jaws, long bones, and ribs
 - Pathologic fractures
 - Renal manifestations:
 - Nephrolithiasis: recurrent and severe; stones composed of calcium phosphate
 - Nephrocalcinosis: presence of bilateral, extensive mineralization in renal pyramids and medullary regions
 - Other manifestations:
 - Conjunctival calcifications
 - Band keratopathy

- Hypertension
- Peptic ulcer disease
- Pancreatitis (acute and chronic)
- Signs and symptoms of severe classical primary hyperparathyroidism, including advanced bone disease and recurrent nephrocalcinosis are uncommon as compared with their incidence two to three decades ago:
- Diffuse osteopenia, with or without compression fractures, articular chondrocalcinosis, and other joint disorders, such as pseudogout and true gout, are currently more frequent findings.
- Biochemical findings include:
 - Elevated serum calcium, which is most accurately reflected by the serum ionized calcium value, because the regulated fraction of calcium is that which is not bound to plasma proteins
 - Decrease in serum inorganic phosphorus resulting from increased urinary loss of phosphates induced by the action of parathyroid hormone at the renal tubular level, as reflected by decreased tubular reabsorption of phosphate or by increased renal phosphate clearance
 - Corresponding increase in urinary cyclic AMP usually accompanies these parathormone-induced alterations in urinary phosphate metabolism
- Serum levels of parathyroid hormone vary depending on the type of assay:
 - Currently preferred assay quantitates intact parathyroid hormone molecule rather than only a cleavage product, as was measured in earlier procedures.
 - Normal serum value for intact parathyroid hormone is 210 to 310 pg/ml.
- Patients with mild symptoms may have significant morbidity due to bone disease.
- Increased mortality rates due to cardiovascular disease may occur.

Secondary Hyperparathyroidism

Definition: An increase in parathyroid parenchymal cell mass of multiple glands in response to a known clinical stimulus for increased secretion of parathyroid hormone. These conditions are usually characterized by hypocalcemia and hyperphosphatemia.

Tertiary Hyperparathyroidism

Definition: An absolute increase in parathyroid parenchymal cell mass associated with autonomous hyperfunction and resultant hypercalcemia in a patient with previously known secondary hyperparathyroidism following implementation of dialysis or renal transplantation.

BOX 31-3 Causes of Hypoparathyroidism Due to Parathyroid-Related Disorders

- Iatrogenic:
 - Postsurgical removal of parathyroid glands
 - Following ^{131}I ablative therapy
- Agenesis
- Familial hypoparathyroidism
- Idiopathic or autoimmune hypoparathyroidism
- Secondary tumors
- Pseudohypoparathyroidism

HYPOPARATHYROIDISM

Definition: Clinical disorder characterized by hypocalcemia and hyperphosphatemia due to deficiency in parathyroid hormone.

Clinical

- Causes of hypoparathyroidism due to parathyroid-related disorders are listed in [Box 31-3](#).
- Hypoparathyroidism may occur as a transient (acute) phenomenon or as a chronic disease.
 - Transient acute hypoparathyroidism may occur following parathyroid or thyroid surgery or following radioactive iodine ablation therapy:
 - Hypocalcemia is mild and may not require treatment.
 - Chronic hypoparathyroidism is uncommon; causes include:
 - Iatrogenic:
 - Postsurgical removal of parathyroid glands
 - Following ^{131}I ablative therapy of the thyroid gland in the treatment of Graves disease
 - Agenesis:
 - Complete or partial failure of development
 - Develops in association with other third and fourth branchial pouch abnormalities, including the thymus and thyroid C-cells, as in DiGeorge syndrome, which is characterized by:
 - ◻ Absence of cell-mediated immunity
 - ◻ Hypoparathyroidism
 - ◻ Congenital defect of the heart and great vessels
 - ◻ DiGeorge syndrome may be a neurocristopathy.
 - Association with other congenital defects in a syndrome referred to as 22q11.2 deletion syndrome or CATCH 22 syndrome:
 - ◻ Cardiac defect, Abnormal facies, Thymic hypoplasia, Cleft palate, Hypocalcemia, and 22q11 deletion
 - ◻ Includes DiGeorge syndrome, conotruncal anomaly face syndrome, and velocardiofacial syndrome.

- GATA-3:
 - Transcription factor functionally involved with the development of parathyroid glands (as well as) breast, urothelial, epidermal, T lymphocyte
 - Mutations in GATA-3 result in hypoparathyroidism characterized by hypocalcemia and low PTH
- Familial hypoparathyroidism:
 - Congenital or inherited mutation of a transcription factor called glial cell missing homolog B (*GCMB*) (6p23) expressed in the PTH-secreting cells of the developing parathyroids.
 - Several mutations in *GCMB* reported to cause hypoparathyroidism
 - Gene responsible for X-linked recessive hypoparathyroidism linked to Xq26-Xq27
- Idiopathic or autoimmune hypoparathyroidism:
 - Seen in conjunction with autoimmune polyglandular syndrome (APS) type I syndrome also referred to as autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED):
 - Rare autosomal-recessive disorder caused by mutation of a single gene named autoimmune regular gene (*AIRE*), which results in a failure of T-cell tolerance within the thymus
 - Disorder by chronic mucocutaneous candidiasis, chronic hypothyroidism, and Addison disease
 - Patients have antibodies directed against other endocrine organs such as adrenal glands, ovaries, thyroid gland.
- Secondary tumors and/or infiltrative disease, including:
 - Metastatic tumors
 - Iron overload such as hemochromatosis and in patients with thalassemia major following numerous transfusions
 - Copper deposition in Wilson disease
- Pseudohypoparathyroidism:
 - Idiopathic and inherited forms of PTH resistance characterized by end-organ resistance to parathyroid hormone due to partial deficiency of the α subunit of the stimulatory G protein ($G_{s\alpha}$), encoded by the *GNAS* gene resulting in low serum calcium, high serum phosphate, and appropriately high serum parathyroid hormone
 - Albright hereditary osteodystrophy (AHO), also known as pseudohypoparathyroidism, type 1a includes:
 - Hypocalcemia and hyperphosphatemia
 - Short stature
 - Rounded face
 - Foreshortened fourth metacarpals
 - Obesity
 - Subcutaneous calcifications
 - Defect in the PTH receptor or in its cAMP-mediated signal transduction
 - Measurement of cAMP in urine following infusion of synthetic PTH is used to establish the diagnosis of PTH resistance.
 - Subclassification into five disorders based on presence of AHO and renal resistance to PTH
 - Pseudopseudohypoparathyroidism is used to refer to patients with the phenotype of AHO but with normal biochemical parameters (lack of PTH unresponsiveness).
- Predominant clinical signs and symptoms of hypocalcemia are:
 - Neuromuscular irritability, including:
 - Perioral paresthesias
 - Tingling in the fingers and toes
 - Tetany (spontaneous or latent):
 - Chvostek sign: ipsilateral contractions of the facial nerve on percussion of the facial nerve below the zygoma
 - Trousseau sign: carpal spasm (may be painful) following 3 minutes of occlusive pressure with a blood pressure cuff
 - EKG abnormalities from hypocalcemia include:
 - Prolonged QT intervals
 - Marked QRS and ST segment changes that may mimic acute myocardial infarction or conduction abnormalities
 - Ventricular arrhythmias (rare complication of hypocalcemia)
 - CNS abnormalities:
 - Convulsions
 - Irritability and depression
 - Psychosis
 - Basal ganglia calcifications with extrapyramidal manifestations
 - Increased intracranial pressure with papilledema
- Total serum calcium includes free (biologically active) and protein bound components, and the major binding protein is albumin:
 - Measurements of total calcium must include concurrent measurement of albumin.
- In comparison to nonparathyroid related hypocalcemia, parathyroid dysfunction includes:
 - Low serum calcium due to lack of PTH-mediated bone resorption and urinary calcium reabsorption

- Increased serum phosphate due to impaired renal function
- Low serum $1,25(\text{OH})_2\text{D}_3$ and decreased $1,25(\text{OH})_2\text{D}_3$ intestinal calcium absorption (further exacerbating the hypocalcemia)
- Low or undetectable PTH levels:
 - PTH levels may be inappropriately normal if some degree of PTH production is preserved.
 - Elevated PTH levels may be present in syndrome associated with resistance to the biologic effects of PTH.
- Acute hypocalcemia is a medical emergency requiring prompt attention:
 - In the presence of neuromuscular irritability, IV calcium is administered until the effects of hypocalcemia abate.
- Treatment of hypocalcemia should be directed at its underlying cause and includes exogenous calcium and vitamin D replacement therapy.
- Vigilant monitoring of the patient to assess efficacy of treatment and to prevent complications is indicated:
 - Daily monitoring of serum calcium for the first month of therapy
 - Measurement of serum PTH and 24-hour urinary calcium excretion is performed within 2 to 4 weeks of institution of therapy.

Non-Neoplastic Lesions of the Parathyroid Glands

CLASSIFICATION OF NON-NEOPLASTIC LESIONS OF THE PARATHYROID GLANDS

(Box 32-1)

BOX 32-1 Non-Neoplastic Lesions of the Parathyroid Glands

- Parathyroid hyperplasia
 - Primary chief cell hyperplasia
 - Water-clear cell hyperplasia
- Parathyroiditis
- Parathyroid cyst

PRIMARY CHIEF CELL HYPERPLASIA (Figs. 32-1 through 32-5, Table 32-1)

Definition: Non-neoplastic increase in parenchymal cell mass of multiple parathyroid glands in the absence of a known clinical stimulus for increased secretion of parathyroid hormone.

Clinical

- Responsible for approximately 13% of cases of hyperparathyroidism
- An autopsy incidence of 7% has been reported.

Fig. 32-1. Parathyroid hyperplasia.

This gland was one of three enlarged glands in a patient with primary hyperparathyroidism. The gland has a variegated nodular appearance.

- Affects females more often than males (F:M = 3:1); incidence increases with age
- Occurrence:
 - Sporadic cases represent 80% of patients with primary chief cell hyperplasia.
 - 20% have familial disease, usually associated with one of the multiple endocrine neoplasia syndromes, although familial parathyroid hyperplasia without other endocrine abnormalities also occurs.
- See under hyperparathyroidism for signs, symptoms, and laboratory findings (see Chapter 31).
- Approximately 20% of patients with primary chief cell hyperplasia have one of the multiple endocrine neoplasia syndromes (MEN):
 - Association is most frequent in MEN type 1 (MEN-1, Wermer syndrome).
 - Parathyroid proliferative disease is seen in 30% to 40% of patients with MEN-2A (Sipple syndrome), but is rare in MEN-2B (Gorlin syndrome).
- MEN-1 (Wermer syndrome) includes:
 - Autosomal-dominant transmission with variable penetrance:
 - Germline mutation on chromosome 11q13

Fig. 32-2. Parathyroid hyperplasia.

The multinodular appearance of this gland is the result of proliferation of groups of cells with different cytologic features; the entire gland is affected by the proliferative process; no rim of normal parathyroid tissue is seen.

Fig. 32-3. Parathyroid hyperplasia.

A, The nodules within the gland are composed of those with clear cells and another with oncocytic cells.

B, Different areas of the same hyperplastic gland may contain predominantly chief cells (*left*) or oncocytic cells (*right*).

- 90% of patients have parathyroid hyperplasia; less often associated with parathyroid neoplasms (adenoma and carcinoma)
- Pancreatic or duodenal endocrine tumors (gastrinoma, insulinoma, glucagonoma)
- Gastrointestinal endocrine cell hyperplasia or neoplasia (functioning and nonfunctioning)
- Anterior pituitary adenoma (functioning and nonfunctioning)
- Some patients also develop pulmonary and thymic neuroendocrine neoplasms, adrenal cortical neoplasms, and thyroid follicular neoplasms.
- MEN-2:
 - Includes MEN-2A (Sipple syndrome) and MEN-2B (Gorlin syndrome)
 - MEN-2A and MEN-2B:
 - Autosomal-dominant transmission:
 - Germline mutations in *RET* proto-oncogene located on chromosome 10q11.2

Fig. 32-4. Parathyroid hyperplasia.

The hyperplastic features may be unevenly distributed among the four glands or even within a single gland. *Left*, Nodules and areas of solid growth with high cellularity. *Right*, Area showing a higher percentage of lipocytes admixed with diffuse cellular areas of chief cells and scattered small oncocytic nodules.

Fig. 32-5. Recurrent parathyroid hyperplasia.

Recurrent parathyroid hyperplasia in parathyroid auto-grafted into the forearm. This patient had a history of chronic renal failure with secondary hyperparathyroidism. His hypercalcemia recurred several months after subtotal parathyroidectomy with autoimplantation of portions of parathyroid gland into the soft tissue of the forearm. The irregular islands of cellular parathyroid tissue may appear to be infiltrating skeletal muscle. This pattern, and even the presence of mitotic figures in the parathyroid tissue, do not indicate malignancy.

- MEN-2A (Sipple syndrome):
 - Characterized by development of bilateral C-cell hyperplasia, thyroid medullary carcinoma, pheochromocytoma, and parathyroid hyperplasia
- MEN-2B (Gorlin syndrome): characterized by development of bilateral C-cell hyperplasia,

TABLE 32-1 Comparative Features of Parathyroid Proliferative Diseases

	Hyperplasia	Adenoma	Carcinoma
Gender; age	Slight female predilection; most common in 5th-6th decades	More common in women; most common in 4th decade	Equal gender predilection; wide age range
Clinical	Asymptomatic or complaints of lethargy, weakness, polyuria, polydipsia, arthralgia, constipation, and depression	Similar to hyperplasia	Similar to hyperparathyroidism of benign etiology but more severe due to the higher serum calcium levels; higher proportion of renal disease (nephrolithiasis) and bone disease; peptic ulcer disease; palpable neck mass more common than in adenoma
Serum calcium	11.7 mg/dl (average)	12.5 to 13.5 mg/dl	Often >14 mg/dl
Intraoperative findings	2 or more glands enlarged, easily dissected; enlargement may be asymmetric	1 gland enlarged; easily dissected; more frequent in lower glands or ectopic sites	1 gland enlarged; often adherent to surrounding tissues
Weight	Total gland weight usually <1 g, but may be up to 5 g	0.3 to 1.0 g commonly, but may weigh several grams in patients with bone disease	>1.5 g (often much larger)
Capsule	Circumscribed by capsule of parathyroid gland, may be incomplete No compressed rim of atrophic or normal parathyroid tissue	Thin tumor capsule, often surrounded by rim of uninvolved parathyroid, which may appear atrophic	Thickened capsule; rim of normal parathyroid rarely seen
Gross appearance	Gray-brown, soft Cut surface may be homogeneous or nodular Lacks fibrous bands	Red-brown, firm Usually homogeneous, lacks fibrous bands but may appear nodular	Gray-white, firm, often lobulated or irregular Fibrous bands often produce coarse nodularity
Histologic pattern	Diffuse or nodular, sometimes follicular or acinar	Diffuse or nodular, frequently follicular or acinar	Predominantly solid or diffuse; may include trabecular, organoid, spindle, or follicular
Cytologic features	Chief cells predominate; transitional and oncocytic cells often present	Chief cells predominate, but mixture of chief, transitional, and oncocytic cells may be seen; rarely, purely oncocytic	Cells usually resemble chief cells, but variable cytoplasmic oncocytic change may be seen; cell borders often indistinct
Intracytoplasmic lipid	Decreased	Decreased in tumor; abundant in atrophic rim of parathyroid	Usually absent
Stromal fat cells	Scanty to absent	Usually absent in tumor; present in rim of atrophic parathyroid	Absent
Nuclear morphology	Normal to slightly increased N-to-C ratio; usually without nuclear pleomorphism	Nuclei enlarged, with variability in size; scattered groups of large pleomorphic, hyperchromatic nuclei, or multinucleated cells	Increased N-to-C ratio; enlarged atypical nuclei; often with very monotonous (bland appearing) nuclei
Nucleoli	Inconspicuous to small	Inconspicuous to small	Frequently prominent and enlarged
Mitoses	Common (60% of cases; most with <1 mitotic figure/10 HPF)	Common (70% of cases; most with <1 mitotic figure/10 HPF)	Common (80% of cases), may include atypical mitoses
Capsular and vascular invasion	Absent	Absent; entrapment of tumor cells may occur in capsule if degenerative changes present	Capsular invasion present in two thirds; may involve only capsule or extend into adjacent tissues Vascular invasion present in up to 15%; usually in capsular vessels

TABLE 32-1 Comparative Features of Parathyroid Proliferative Diseases—cont'd

	Hyperplasia	Adenoma	Carcinoma
Remainder of gland	Entire gland is abnormal	Normal or atrophic	Normal
Degenerative changes	May be seen in very large glands; includes hemorrhage, areas of fibrosis, and cystic change	Common, especially in larger adenomas; includes hemorrhage, fibrosis, and cystic change, sometimes calcification	Tumor cell necrosis; calcification and cystic changes may be present
Treatment	Subtotal parathyroidectomy with surgical removal of three glands leaving a remnant of the fourth or total parathyroidectomy* with autotransplantation of parathyroid tissue in forearm	Surgical removal of the enlarged gland	En bloc resection, including ipsilateral thyroid lobe and adjacent soft tissues
Prognosis	Excellent	Excellent	Up to 50% of patients are cured by en bloc resection; considered an indolent malignancy even in presence of recurrence or metastasis with long survival even after recognition of tumor recurrence; morbidity and mortality correlate to complications of severe hypercalcemia
Recurrence and metastasis	Recurrence in approximately 16% of cases due to inadequate neck exploration and may not be evident for years	Absent	Recurrence in two thirds of patients usually within 3 years of the first surgery; metastasis is 35%, is a late event usually preceded by local recurrence; most commonly to lung, cervical lymph nodes, and liver
Familial and/or MEN association	Yes, in approximately 20% of cases	Uncommon	Rare

g, Grams; HPF, high power fields; MEN, multiple endocrine neoplasia syndrome; N-to-C, nuclear-to-cytoplasmic.

*Particularly in cases of familial hyperparathyroidism.

medullary thyroid carcinoma, pheochromocytomas, and oral and gastrointestinal ganglioneuromatosis

Radiology

- Radiographic imaging techniques applied to localization of hyperfunctioning parathyroid glands include retrograde phlebectomy with serum parathormone assays, CT scanning, ultrasonography, magnetic resonance imaging (MRI), thallium subtraction scanning, and technetium-99m sestamibi imaging.
- Imaging procedures have been significantly less effective in localizing glands in cases of hyperplasia as compared with parathyroid adenomas or carcinomas.
- Technetium-99m sestamibi has been effective in localizing up to 60% of hyperplastic glands; it has been more widely used in the evaluation of patients

with recurrent hyperparathyroidism after parathyroid resection.

Pathology

Cytology

- Cytologic findings in aspirate smears of parathyroid hyperplasia and parathyroid adenoma are indistinguishable and allow only documentation of “parathyroid proliferative disease.”

Gross

- Although all four glands may be enlarged, it is not uncommon for hyperplasia to be somewhat asymmetric, with two or three glands being much larger than the others.
- In some cases one gland is so much larger than the others that the gross appearance suggests an adenoma, emphasizing the importance of sampling

grossly “normal” glands to facilitate accurate discrimination between hyperplasia and adenoma, because increased cellularity of the smaller glands may be the key to recognizing the multiglandular nature of the proliferation.

- Glands may be diffusely enlarged or may be nodular, particularly with increasing size.
- Cystic change may be present but is not common.
- Total gland weight in primary chief cell hyperplasia is variable and has been reported as:
 - <1 g in 54% of patients
 - 1 to 5 g in 28% of patients
 - 5 to 10 g in 18% of patients
- Glands are usually soft and tan-brown
- Distinction between hyperplastic and adenomatous glands generally cannot be made by gross examination.

Histology

- Primary chief cell hyperplasia results from an increase in parenchymal cell mass, predominantly involving chief cell proliferation; however, oncocytic cells may be present as well.
- Chief cell hyperplasia may be diffuse or nodular:
 - Chief cells may be arranged in solid sheets, cords, acinar-like, or follicular structures or commonly mixed patterns are identified.
 - Variable nodularity
 - Nodules may be small (micronodular), solitary, or multiple.
- Small follicular structures may contain PAS-positive material resembling dense colloid; this material is thyroglobulin negative.
- Stromal fat cells are absent or markedly decreased in number in most areas, although foci of stromal fat cells may mimic normal gland:
 - Variations in distribution of fat cells and variability in the density of the chief cells, particularly in a nodular hyperplasia, may yield a confusing histologic picture.
 - Areas with residual fat may mimic a rim of “normal” gland, particularly when they are adjacent to large nodules, which generally lack fat cells, may suggest a diagnosis of adenoma, again emphasizing the importance of microscopic examination of multiple glands and the need for processing multiple sections of larger glands.
- Although circumscribed by the delicate fibrous capsule of the gland, hyperplasia may also involve nests of parathyroid tissue in the soft tissue of the neck (“parathyromatosis”):
 - This phenomenon may be the cause of recurrent disease after an apparently complete resection of the grossly evident hyperplastic glands.
 - Should not be mistaken for “invasion” as one would see in carcinoma; the lack of a fibroblastic

reaction or infiltrative contour, absence of an intravascular location of these nests, and lack of other histologic features of carcinoma should help exclude malignancy.

- Hyperplastic cells usually contain less intracytoplasmic fat than normal or atrophic parathyroid tissue when demonstrated by oil red O or Sudan black stains; however, some hyperplastic parathyroid tissue may contain abundant intracytoplasmic fat:
 - Intracytoplasmic fat may be more abundant in the chief cells between hyperplastic nodules, whereas it is usually absent in cells within the nodules.
 - The term lipohyperplasia has been used in cases of hyperplastic glands with abundant fat:
 - Presence of fat in this setting makes the diagnosis of hyperplasia challenging.
 - Biopsies may contain only fat or be predominantly of fat with limited parenchymal cells.
 - The clinical setting and enlargement of multiple glands is important in the diagnosis of lipohyperplasia.
- Although mitotic figures may be seen, they usually number less than 1 per 10 high-power fields; some cases demonstrate mitotic rates of 1 to 5 per 10 high-power fields; however, atypical mitoses are not present.
- Immunohistochemistry:
 - Chief cells are positive for parathyroid hormone (PTH), parafibromin (nuclear), cytokeratins, chromogranin A:
 - Staining for PTH and chromogranin A is less intense as compared with normal (nonhyperplastic) chief cells.
 - Calcitonin and synaptophysin typically negative but in small percentage of cases may be focally positive
 - PAX8 (nuclear) reactivity present in approximately 40% of hyperplasia and adenomas
 - Negative for thyroglobulin and TTF-1
- Electron microscopy:
 - Cells contain abundant mitochondria, endoplasmic reticulum, and large Golgi areas, as well as characteristic secretory granules.
- Cytogenetics and molecular genetics:
 - Chief cell hyperplasia associated with MEN: see previously

Differential Diagnosis

- Parathyroid proliferative disease, especially adenoma and also carcinoma ([Table 32-1](#))
- Lithium therapy for psychiatric disorders has been associated with a form of hyperparathyroidism similar to primary hyperparathyroidism with hypercalcemia and elevated serum parathormone levels;

chief cell hyperplasia and “adenomas” have been described in these patients:

- Hyperparathyroidism resolves after discontinuing lithium therapy
- Patients requiring lithium may be treated successfully with subtotal parathyroidectomy.
- Humoral hypercalcemia of malignancy (HHM) is an important clinical differential diagnostic consideration in patients suspected of having primary hyperparathyroidism:
 - HHM is independent of the extent of metastatic disease involving bone and is characterized by hypercalcemia, hypophosphatemia, and elevated urinary cyclic AMP levels.
 - Unlike hyperparathyroidism, serum parathormone, and 1,25-dihydroxyvitamin D are suppressed.
 - Mechanism for hypercalcemia appears to be increased bone resorption due to a humoral factor known as parathyroid hormone-related protein.
 - This form of hypercalcemia was most frequent in patients with squamous cell carcinoma (lung, upper aerodigestive tract, and female genital tract), renal cell carcinoma, and transitional cell carcinoma.
 - A second mechanism of hypercalcemia associated with malignancy is related directly to the osteolytic effect of bone metastases; this form of hypercalcemia is more common in patients with breast carcinoma and hematologic malignancies; these patients have suppressed levels of parathormone, but urinary cyclic AMP is not elevated and parathyroid hormone-related protein has not been implicated.
- Familial benign hypercalcemia or familial hypocalciuric hypercalcemia:
 - Autosomal-dominant condition
 - Caused by inactivating mutations in the calcium sensing receptor (*CASR*) gene, leading to a general calcium-hyposensitivity, compensatory hypercalcemia, and hypocalciuria
 - Should be suspected in young patients with presumptive diagnosis of hyperparathyroidism and family history
 - Hypercalcemia often starts in childhood.
 - Persistent hypercalcemia following subtotal parathyroidectomy for presumed primary hyperparathyroidism
 - Many patients are asymptomatic or have vague symptoms.
 - Signs and symptoms of hypercalcemia are rare.
 - Calcium:creatinine clearance ratio is traditional test to diagnose this disorder:
 - Patients have low urinary calcium excretion relative to serum calcium levels, elevated serum

magnesium levels, parathyroid hormone levels are usually elevated but lower than in primary hyperparathyroidism

- Histologically, parathyroid glands are normal or show mild chief cell hyperplasia.

Treatment and Prognosis

- Subtotal parathyroidectomy with complete removal of three glands, leaving a remnant of the fourth, is the most widely accepted therapy.
- Total parathyroidectomy with autotransplantation of remnants of parathyroid tissue in the forearm is also a common surgical therapy.
- Recurrence rate of hyperparathyroidism following subtotal parathyroidectomy is approximately 16%:
 - Recurrences may not be evident for several years.
 - Recurrences may be due to inadequate neck exploration, which may result from diagnosis of “adenoma” in cases of asymmetric hyperplasia.
 - Less frequent causes include failure to recognize supernumerary or ectopic glands, parathyromatosis, or surgical implantation of hyperplastic tissue in the soft tissue of the neck.

WATER-CLEAR CELL HYPERPLASIA (Figs. 32-6 and 32-7)

Definition: Non-neoplastic increase in parenchymal cell mass of multiple parathyroid glands by proliferation of large cells with clear, vacuolated cytoplasm, in the absence of a known clinical stimulus for increased secretion of parathyroid hormone.

Synonym: Wasserhelle cell hyperplasia

Fig. 32-6. Water-clear cell hyperplasia.

In water-clear cell hyperplasia the glands are usually markedly enlarged and are replaced by a diffuse proliferation of clear cells with no stromal fat, although in other examples, limited intraparenchymal fat may be present.

Fig. 32-7. Water-clear cell hyperplasia.

In contrast to the cells in chief cell hyperplasia, the cells in water-clear cell hyperplasia show more abundant, clear appearing cytoplasm, a much lower nuclear-to-cytoplasmic ratio, and the presence of distinct cell membranes.

Clinical

- Slightly more common in men than in women (M:F = 1.4:1); most common in fifth decade
- Very rare cause of hyperparathyroidism:
 - Reason for the virtual disappearance of water-clear cell hyperplasia in the population is not known; some suggest that it represents an advanced form of primary chief cell hyperplasia.
 - Decreasing incidence and severity of chief cell hyperplasia as a result of routine biochemical screening of patients lends some support to this theory
 - Electron microscopic appearance of water-clear cell hyperplasia sufficiently distinctive from primary chief cell hyperplasia to doubt that it develops from pre-existing chief cell hyperplasia
- Hypercalcemia and symptoms are usually more severe than in chief cell hyperplasia:
 - Mean serum calcium, 13.2 mg/dl, compared with 11.7 mg/dl in cases of chief cell hyperplasia
- Nephrolithiasis occurs in 90% of patients, in contrast to a rate of 53% of patients with chief cell hyperplasia during the same period.
- Overall incidence of bone disease similar to chief cell hyperplasia, with occasional patients presenting with osteitis fibrosa cystica
- No documented association with multiple endocrine neoplasia or other familial syndromes

Pathology

Gross

- Usually all four glands are enlarged, although asymmetry is common, and the upper glands are often larger than the lower glands.

- Mean total gland weight >10 g in 47% of cases; combined weight under 1 g not reported
- Involved glands are dark brown and may exhibit cystic change, areas of fibrosis, or hemorrhage; nodularity within the glands is uncommon, but the gland contour is often irregular.

Histology

- Glands are usually diffusely replaced by large clear cells, with little or no remaining stromal adipose tissue.
- Cells are from 10 to 40 μ in diameter, with distinct cell borders arranged in sheets, cords, or sometimes in acinar groups.
- Cytoplasm appears clear with distinct cell membranes but may contain many small vacuoles, which give a finely reticulated pattern in hematoxylin-eosin stained sections:
 - Vacuoles are more readily apparent in plastic-embedded thin sections.
 - Glycogen is demonstrable in the cytoplasm with periodic acid Schiff.
 - Neutral fat stains are negative.
- Nuclei are small, round to ovoid, rather hyperchromatic, and are basally oriented in the polyhedral to slightly columnar cells.
- Scattered multinucleated cells and occasional large hyperchromatic nuclei may be observed.
- Immunohistochemistry:
 - Parathyroid hormone (PTH), parafibromin (nuclear), cytokeratins, chromogranin A positive:
 - Staining for PTH and chromogranin A less intense as compared with normal (nonhyperplastic) chief cells
 - Calcitonin staining may focally be present.
 - Cyclin D1 expression present in majority of cases (approximately 61%)
 - Negative for thyroglobulin and TTF-1
- Electron microscopy:
 - Clear cells contain numerous membrane-bound vacuoles, many of which appear “empty”; however, some contain electron-dense material similar to the smaller typical parathyroid secretory granules, which are also scattered through the cytoplasm.

Differential Diagnosis

- Primary chief cell hyperplasia
- Parathyroid adenoma (particularly if only one gland has been sampled or if the hyperplasia is very asymmetric)
- Metastatic renal cell carcinoma with differentiation based on the presence in parathyroid hyperplasia of:
 - Biochemical findings of hyperparathyroidism
 - Positive immunohistochemistry for PTH, parafibromin, and chromogranin

- Absence of renal cell carcinoma (RCC) antibody, CD10, PAX2, PAX8, and CAIX
- Follicular thyroid neoplasm with clear cell features:
 - Presence of thyroglobulin, TTF1, and PAX8 differentiates thyroid from parathyroid lesions.

Treatment and Prognosis

- Subtotal parathyroidectomy is the preferred therapy.
- Recurrent hyperparathyroidism found in 45% of cases, probably because too large a remnant of parathyroid gland was preserved at original operation.

SECONDARY HYPERPARATHYROIDISM

Definition: An increase in parathyroid parenchymal cell mass of multiple glands in response to a known clinical stimulus for increased secretion of parathyroid hormone; usually characterized by hypocalcemia and hyperphosphatemia.

Clinical

- Causes of secondary hyperparathyroidism include chronic renal failure (most common), dietary vitamin D deficiency or abnormalities of vitamin D metabolism, malabsorption, and pseudohypoparathyroidism.
- Occurs over broad age range, reflecting the incidence of chronic renal failure, the most common cause of secondary hyperparathyroidism
- Symptoms of secondary hyperparathyroidism are related primarily to parathyroid hormone-mediated bone resorption, which results in osteomalacia and osteitis fibrosa cystica.
- Abnormal calcium deposits may be seen, including:
 - In the soft tissues, particularly in a periarticular distribution
 - Cutaneous calciphylaxis:
 - Uncommon
 - Mainly seen in renal failure-associated hyperparathyroidism
 - Progressive cutaneous vascular calcification
 - Potentially lethal
- Laboratory studies reveal elevation of parathyroid hormone levels with hypocalcemia and hyperphosphatemia.

Pathology

Gross

- Not significantly different from that of primary chief cell hyperplasia; there may be uniform enlargement of all glands or the enlargement may be asymmetric
- Glands are yellow-brown to gray, with weights ranging from 0.12 to 6 g.

Histology

- Proliferation includes chief cells, oncocytic cells, and transitional cells.
- Increased parenchymal cell mass varies depending on the duration of disease, as does the number of residual stromal fat cells:
 - In advanced disease the fat cells are absent.
- Parenchymal cells may grow in sheets, cords, or acinar structures.
- Nodular aggregates of chief cells or oncocytic cells are common in very enlarged glands; areas of fibrosis, cystic change, and calcification may be present.
- Oncocytic cells seem to be a more common component than in primary chief cell hyperplasia.

Differential Diagnosis

- Primary chief cell hyperplasia
- Parathyroid adenoma

Treatment and Prognosis

- Subtotal parathyroidectomy is the preferred treatment:
 - Remnant of parathyroid gland may be left in situ or transplanted to the soft tissue of the forearm.
 - Auto-transplantation of parathyroid tissue into the forearm musculature following total parathyroidectomy may be associated with graft failure and hypoparathyroidism, or with recurrent hyperparathyroidism due to hyperplasia of the transplanted remnant of parathyroid.
- Recurrence of hyperparathyroidism is a common problem in patients with chronic renal failure, since the stimulus for hypersecretion of parathyroid hormone is frequently not correctable.
- Recurrent hyperplasia may be associated with a multifocal proliferation of islands of parathyroid tissue in the adipose tissue and skeletal muscle, sometimes rather widely separated from the original site of transplantation:
 - Hyperplastic cells may be somewhat more pleomorphic than the original parathyroid proliferation and may even be mitotically active.
 - These changes should not be interpreted as evidence of malignancy.

TERTIARY HYPERPARATHYROIDISM

Definition: An absolute increase in parathyroid parenchymal cell mass associated with autonomous hyperfunction and resultant hypercalcemia in a patient with previously known secondary hyperparathyroidism following implementation of dialysis or renal transplantation.

Clinical

- Tertiary hyperparathyroidism occurs over a broad age range, reflecting the incidence of chronic renal failure.
- Hypercalcemia usually develops several years after the diagnosis of renal disease.
- Hypercalcemia due to tertiary hyperparathyroidism represents a serious threat to renal grafts and requires prompt surgical therapy.
- Laboratory findings are similar to those of primary hyperparathyroidism.
 - Increase in parathyroid parenchymal cell mass of multiple glands in response to a known clinical stimulus for increased secretion of parathyroid hormone. These conditions are usually characterized by hypocalcemia and hyperphosphatemia.
- The cause of autonomous hyperfunction of the parathyroids in patients with treated renal failure is not known; an elevation of the “set point” for serum calcium has been postulated; this would result in stimulation of parathyroid tissue in spite of normal serum calcium levels.
- There is also evidence that the sheer mass of parathyroid tissue in patients with tertiary hyperparathyroidism may cause autonomous function.
- Removal of the bulk of the hyperplastic tissue results in a readily suppressible remnant.

Pathology

Gross

- The glands may be diffusely enlarged or nodular. Patients with nodular hyperplasia tend to have more striking, but asymmetric, gland enlargement.
- Parathyroid glands with diffuse hyperplasia are 10 to 20 times the size of normal parathyroid glands; those with nodular hyperplasia were 20 to 40 times normal size.

Histology

- 95% of patients with tertiary hyperparathyroidism have hyperplasia; only 5% are found to have adenomas.
- Chief cells predominate in hyperplasia due to tertiary hyperparathyroidism; however, oncocytic and transitional cells may be seen in either diffuse or nodular hyperplasia. Rarely, areas with water-clear cells may be present.
- Areas of hemorrhage, recent or remote, as well as fibrosis and calcification are common.
- Mitotic figures are uncommon, as is nuclear pleomorphism.
- Stromal fat cells are sparse but are more often present in areas between nodules. This distribution may suggest a diagnosis of “adenoma”; however, multinodularity is more consistent with a hyperplastic process.

Differential Diagnosis

- Parathyroid adenoma:
 - The rare parathyroid adenomas responsible for tertiary hyperparathyroidism are indistinguishable from parathyroid adenomas associated with primary hyperparathyroidism.

Treatment and Prognosis

- Subtotal parathyroidectomy is the preferred therapy.
- Recurrent hyperparathyroidism has been seen in approximately 8% of patients after surgery.

PARATHYROID CYST

(Figs. 32-8 through 32-10)

Definition: Cystic lesion associated with a parathyroid parenchymal cell lining or associated parathyroid tissue in the cyst wall; these lesions may represent either hyperplasia or adenomas with cystic degeneration or developmental cysts (if nonhyperfunctioning).

Clinical

- Rare lesion
- More common in women than in men; occur in adults
- Symptoms may be due to the presence of an asymptomatic neck mass that preoperatively may be mistaken for a thyroid lesion, thyroglossal duct cyst, or branchial cleft cyst; may be incidentally discovered during surgery or by radiographs (especially in the case of mediastinal parathyroid cysts) or, rarely, to hypercalcemia (as in other cases of primary hyperparathyroidism); pressure symptoms may result in symptoms including dyspnea and stridor due to tracheal compression or hoarseness and vocal cord palsy due to compression of the recurrent laryngeal nerve.
- May be nonfunctional or functional with elevated levels of parathyroid hormone
- Patients may be either normocalcemic or hypercalcemic:
 - Hypercalcemia is associated with the usual biochemical pattern of primary hyperparathyroidism.
- Most are located in the neck arising from any of the parathyroid glands although more commonly arise in association with the lower parathyroid glands; mediastinal parathyroid cysts have been reported.
- Rarely reported in association with MEN-1
- Radiology:
 - On imaging parathyroid cysts are large and unilocular with varying MR imaging and CT findings, depending on their protein content.

Fig. 32-8. Parathyroid cysts.

A, Unenhanced axial T1-weighted MR image shows a unilocular 3-cm cyst (*arrows*) in the right paratracheal region, just below the inferior pole of the right thyroid lobe. **B**, Corresponding axial T2-weighted MR image shows the hyperintense cyst. Note the small hemorrhage level (*arrows*) in the dependent portion of the cyst, which was confirmed at pathology. **C** and **D**, Axial contrast-enhanced CT scans show a cystic mass adjacent to the posterior right thyroid lobe. The cyst has nodules within it (*arrows*). This was a functioning parathyroid cyst. **E**, Axial T2-weighted MR image shows a cystic mass behind the left thyroid lobe with a nodule within it (*arrow*). This is a functioning parathyroid cyst. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 41-111, p 2675.)

Fig. 32-9. Parathyroid cyst.

Gross appearance of a (unilocular) parathyroid cyst.

- Origin for parathyroid cysts is unknown; considerations include developmental and degenerative:
 - Developmental due to cystic change in remnants of a branchial pouch or from gland-like structures (called canals of Kürsteiner) in the fetal parathyroid glands
 - Degenerative due to cystic change in a pre-existing lesion (e.g., adenoma, hyperplasia)

Pathology

Cytology

- Fine-needle aspiration has been useful in identification of some parathyroid cysts preoperatively, particularly palpable cervical lesions.
- Aspirated cyst fluid may contain clusters of cells in microacinar or papillary-like groups with the coarse chromatin and finely granular cytoplasm with poorly defined cell borders.
- The cellular component may be difficult to distinguish from follicular thyroid epithelium; immunohistochemistry for thyroglobulin and chromogranin may be helpful if adequate tissue is present.
- Assay of the cyst fluid for parathormone can be used to establish the diagnosis of a parathyroid cyst.

Gross

- Most parathyroid cysts are unilocular with a well-defined capsule and a cyst wall that may be thin and translucent with a gray-white appearance; in some cases the wall has a tan-yellow appearance due to the presence of a rim of parathyroid tissue.
- Cysts vary in size; although many smaller cysts obviously represent cystic change in a parathyroid adenoma, some as large as 10 cm have been described.

Fig. 32-10. Parathyroid cyst.

A, Intraparenchymal unilocular cyst surrounded by islands of normal parathyroid parenchyma. **B**, At higher magnification the cyst is lined by a single flattened layer of chief cells (arrow) histologically similar to the chief cells in the surrounding parathyroid gland.

- The cyst fluid is thin and colorless to yellow, although sometimes it may be bloody; the cyst fluid may be rich in parathyroid hormone.

Histology

- The cyst may be lined by flattened epithelium or by recognizable chief cells.
- Islands of parathyroid tissue are present within or adjacent to the cyst wall; this parathyroid tissue may appear normal or may represent a parathyroid adenoma or a hyperplastic parathyroid gland.

Differential Diagnosis

- Cystic thyroid neoplasm or adenomatoid nodule
- Lymphangioma
- Thymic cyst

- Bronchogenic, neurenteric, or esophageal foregut cysts
- Pericardial or pleural cysts

Treatment and Prognosis

- Preferred treatment is surgical removal.
- If hypercalcemia is present the approach should include investigation of the status of other parathyroid glands intraoperatively if the cyst is cervical or postoperatively if the lesion is intrathoracic.

CHRONIC PARATHYROIDITIS

(Fig. 32-11)

Definition: Infiltration of the parathyroid gland by mature lymphocytes (mixed B- and T-cells) and plasma cells with glandular atrophy and fibrosis.

Synonyms: Autoimmune parathyroiditis; hyperplastic parathyroiditis

Clinical

- Focal lymphocytic infiltrate of the parathyroid glands has been found at autopsy in approximately 10% of patients who were euparathyroid.
- Uncommon finding that may be seen in patients with hypoparathyroidism, or even more rarely in primary chief cell hyperplasia
- Possible autoimmune cause postulated:
 - Histologic changes equivalent to those seen in association with chronic lymphocytic (Hashimoto) thyroiditis, an autoimmune disease
 - In some patients with chronic parathyroiditis there are autoimmune diseases of other organs.
- Experimental model in rabbits has shown induction of autoimmune parathyroiditis following ozone inhalation.

Pathology

Gross

- May be seen in grossly normal glands, as an incidental finding, or in enlarged glands with hyperplasia

Histology

- Scattered aggregates of lymphocytes and plasma cells are present in the gland.
- Parathyroid parenchyma appears nodular separated by fibrous tissue with associated lymphocytes and plasma cells:
 - The inflammatory cell infiltrate may vary from scattered aggregates to diffuse infiltrate.

Fig. 32-11. Chronic parathyroiditis.

Chronic parathyroiditis characterized by a nodular-appearing parenchyma separated by fibrous tissue with associated inflammatory cell infiltrate.

- Lymphoid follicles with or without germinal centers may be present.
- Scattered aggregates of lymphocytes may be found in otherwise normal glands as an incidental finding.

Treatment and Prognosis

- The significance of parathyroiditis is often unclear.
- Clinical findings and treatment are based on the underlying process involving the parenchymal cells if clinically evident disease is present.

Neoplasms of the Parathyroid Glands

CLASSIFICATION OF NEOPLASMS OF THE PARATHYROID GLANDS

(Box 33-1)

BOX 33-1 Neoplasms of the Parathyroid Glands

- Parathyroid adenoma
- Parathyroid carcinoma
- Secondary neoplasms

PARATHYROID ADENOMA

(Figs. 33-1 through 33-22, Table 33-1)

Definition: Benign neoplasm of the parathyroid parenchymal cells, including chief cells and/or oncocytic cells.

Clinical

- More common in females (F:M = 3 to 4:1); occur over a broad age range but are most frequently discovered in the fourth and fifth decades.
- Represents the major cause of primary hyperparathyroidism
- Clinical findings are essentially the same as those associated with primary hyperparathyroidism due to hyperplasia (see Chapter 32).
- As in primary hyperparathyroidism due to hyperplasia, the symptomatology in patients with parathyroid adenomas is changing as a result of routine biochemical screening and early detection:
 - Hypercalcemia may be incidentally discovered in asymptomatic patients, and many patients complain only of fatigue, weakness, or depression.
 - Nephrolithiasis is documented in 69% of men and in 36% of women with adenomas overall, but the incidence has been decreasing in recent years to between 5% and 20%.
 - Severe bone disease, once a common complication, is now rare; however, osteopenia is often present, and joint disease similar to that found in patients with parathyroid hyperplasia occurs.
- Serum calcium levels are generally higher than in patients with primary chief cell hyperplasia but not usually as high as in parathyroid carcinoma.
- Hypophosphatemia, hyperphosphaturia, and elevated serum parathormone levels are found.
- Rarely parathyroid adenomas present as a palpable mass.
- Radiology:
 - Several imaging methods have been used for localization of hyperfunctioning parathyroid tissue, including retrograde phlebotomy for determination of serum parathormone levels, CT scanning, ultrasonography, magnetic resonance imaging (MRI), thallium subtraction scanning, and technetium-99m sestamibi imaging.
 - Technetium-99m sestamibi imaging appears to be the most useful, with localization of more than 90% of adenomas, and has been most widely used in patients with anatomic distortion due to previous surgery and in patient who are high surgical risks; however, more routine utilization has gained support.
 - Multidimensional CT (referred to as 4D-CT) emerging technique used in detection when a lesion is not identified by more conventional techniques (e.g., ultrasonography, sestamibi imaging)
- May be associated with hyperparathyroidism-jaw tumor syndrome (HPT-JT):
 - Autosomal-dominant disorder with germline mutation in *HRPT-2* gene on chromosome 1q25-31
 - Characterized by:
 - Parathyroid adenoma or carcinoma
 - Fibro-osseous lesions of the jaw (e.g., ossifying fibroma of mandible or maxilla): 30% of cases
 - Renal cyst, hamartoma, carcinoma: 20% of cases
 - Approximately 80% of patients develop hyperparathyroidism:
 - Usually presents late in adolescence
 - Hypercalcemia tends to be severe.
 - Higher incidence of parathyroid carcinoma in comparison with patients with MEN-1 and MEN-2A
 - Renal lesions may include:
 - Renal cysts, polycystic renal disease, renal hamartoma
 - Papillary renal cell carcinoma, renal cortical adenomas, Wilms tumor
- 90% of adenomas are found in parathyroid glands in their usual locations:
 - Lower glands are more commonly involved.

Fig. 33-1. Classic parathyroid adenoma identified on ultrasonography.

A, Sagittal ultrasonographic image shows a hypoechoic, well-defined mass (A) just below the inferior pole of the right thyroid gland (*). **B**, Transverse ultrasonographic image with color flow Doppler shows the increased peripheral arch of vascularity of the mass frequently seen with adenomas (A). (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 41-95, p 2663.)

- Ectopic parathyroid adenomas:
 - Parathyroid adenomas may occur in any location in which parathyroid tissue may be found, including ectopic sites such as the mediastinum, retroesophageal soft tissue, within the thyroid gland, or in thymic tissue
 - Ectopic adenomas, especially intrathyroidal ones, may be missed by clinical evaluation and/or surgical exploration:
 - Intrathyroidal parathyroid adenomas may be misinterpreted by pathologic evaluation as a thyroid follicular lesion or medullary thyroid carcinoma.

- Reports of adenomas occurring in supernumerary glands include tumors arising in the vagus nerve, pericardium, or other soft tissue sites in the neck.

Pathology

Cytology

- Occasionally enlarged parathyroid glands, either hyperplastic or, more commonly, adenomatous, have been serendipitously subjected to fine-needle aspiration as a clinically suspected “solitary thyroid nodule”; reports of ultrasonically guided fine-needle aspiration for localization and confirmation of parathyroid proliferative disease have appeared.
- An awareness of the typical cytologic appearance of parathyroid tissue can be helpful during intraoperative examination of biopsies during a neck exploration for hyperparathyroidism, as examination of touch preparations provides a rapid means of confirming the presence of parathyroid tissue.
- Aspirates of parathyroid tissue typically contain numerous naked nuclei, as well as small sheets of cells, sometimes forming acinar or follicular structures; small aggregates of dense colloid-like material may be seen but are not numerous.
- The cells are generally small, with predominantly round nuclei; anisonucleosis in scattered cells and occasional large, atypical, naked nuclei are common.
- The cytoplasm is granular and may exhibit scattered large metachromatic granules with a May-Grünwald-Giemsa or Romanowsky stain; Papanicolaou-stained cells have clear to finely granular cytoplasm.
- The nuclei are generally hyperchromatic with coarse chromatin typical of neuroendocrine cells.
- The distinction from follicular epithelium of the thyroid may be difficult, although the cells are usually smaller than those of the thyroid:
 - Immunohistochemical staining for PTH, parafibrin, chromogranin, thyroglobulin, and TTF1 may be helpful in this differential diagnosis.

Gross

- Adenomas are almost always solitary (see below for Double Adenoma).
- Adenomas have rounded borders, are firm, brown to tan, and are contained within a delicate capsule; they may be ovoid or lobulated.
- A remnant of uninvolved parathyroid tissue at the periphery of the tumor may be visible.
- Cystic change may be present, and when marked may mask the neoplastic nature of the proliferation; marked cystic degeneration is frequently associated with scarring and calcification.
- There is significant variation in weight, with most between 0.3 and 1.0 g.

Fig. 33-2. Parathyroid adenoma.

Parathyroid adenoma detected by $^{201}\text{Tl}/^{99\text{m}}\text{Tc}$ -pertechnetate subtraction imaging (**A** to **C**) and by $^{99\text{m}}\text{Tc}$ -sestamibi subtraction imaging with ^{123}I (**D**). **A**, $^{99\text{m}}\text{Tc}$ -pertechnetate concentrated within the thyroid gland. **B**, ^{201}Tl concentrated within thyroid and parathyroid glands. **C**, Computer techniques allow technetium concentrated in the thyroid gland to be subtracted from thallium that accumulates within thyroid and parathyroid tissue. After thyroid subtraction, a parathyroid adenoma is noted as a focus of increased thallium uptake (arrows). **D**, $^{99\text{m}}\text{Tc}$ -sestamibi subtraction imaging with ^{123}I shows an adenoma below the inferior pole of the left lobe of the thyroid gland. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 41-103, p 2669.)

Histology

- Well circumscribed and uncommonly surrounded by a thin fibrous capsule:
 - Complete encapsulation not commonly seen
- Hypercellular proliferation lacking intraparenchymal fat cells with diffuse growth; vague nodularity may be present and rarely may be multinodular.
- A rim of non-neoplastic parathyroid tissue found in association with only about half of the adenomas:
 - Very helpful finding, if present, in making the distinction between adenoma and hyperplasia
 - “Rim” generally contains abundant stromal fat cells, in contrast to the very cellular adenoma.

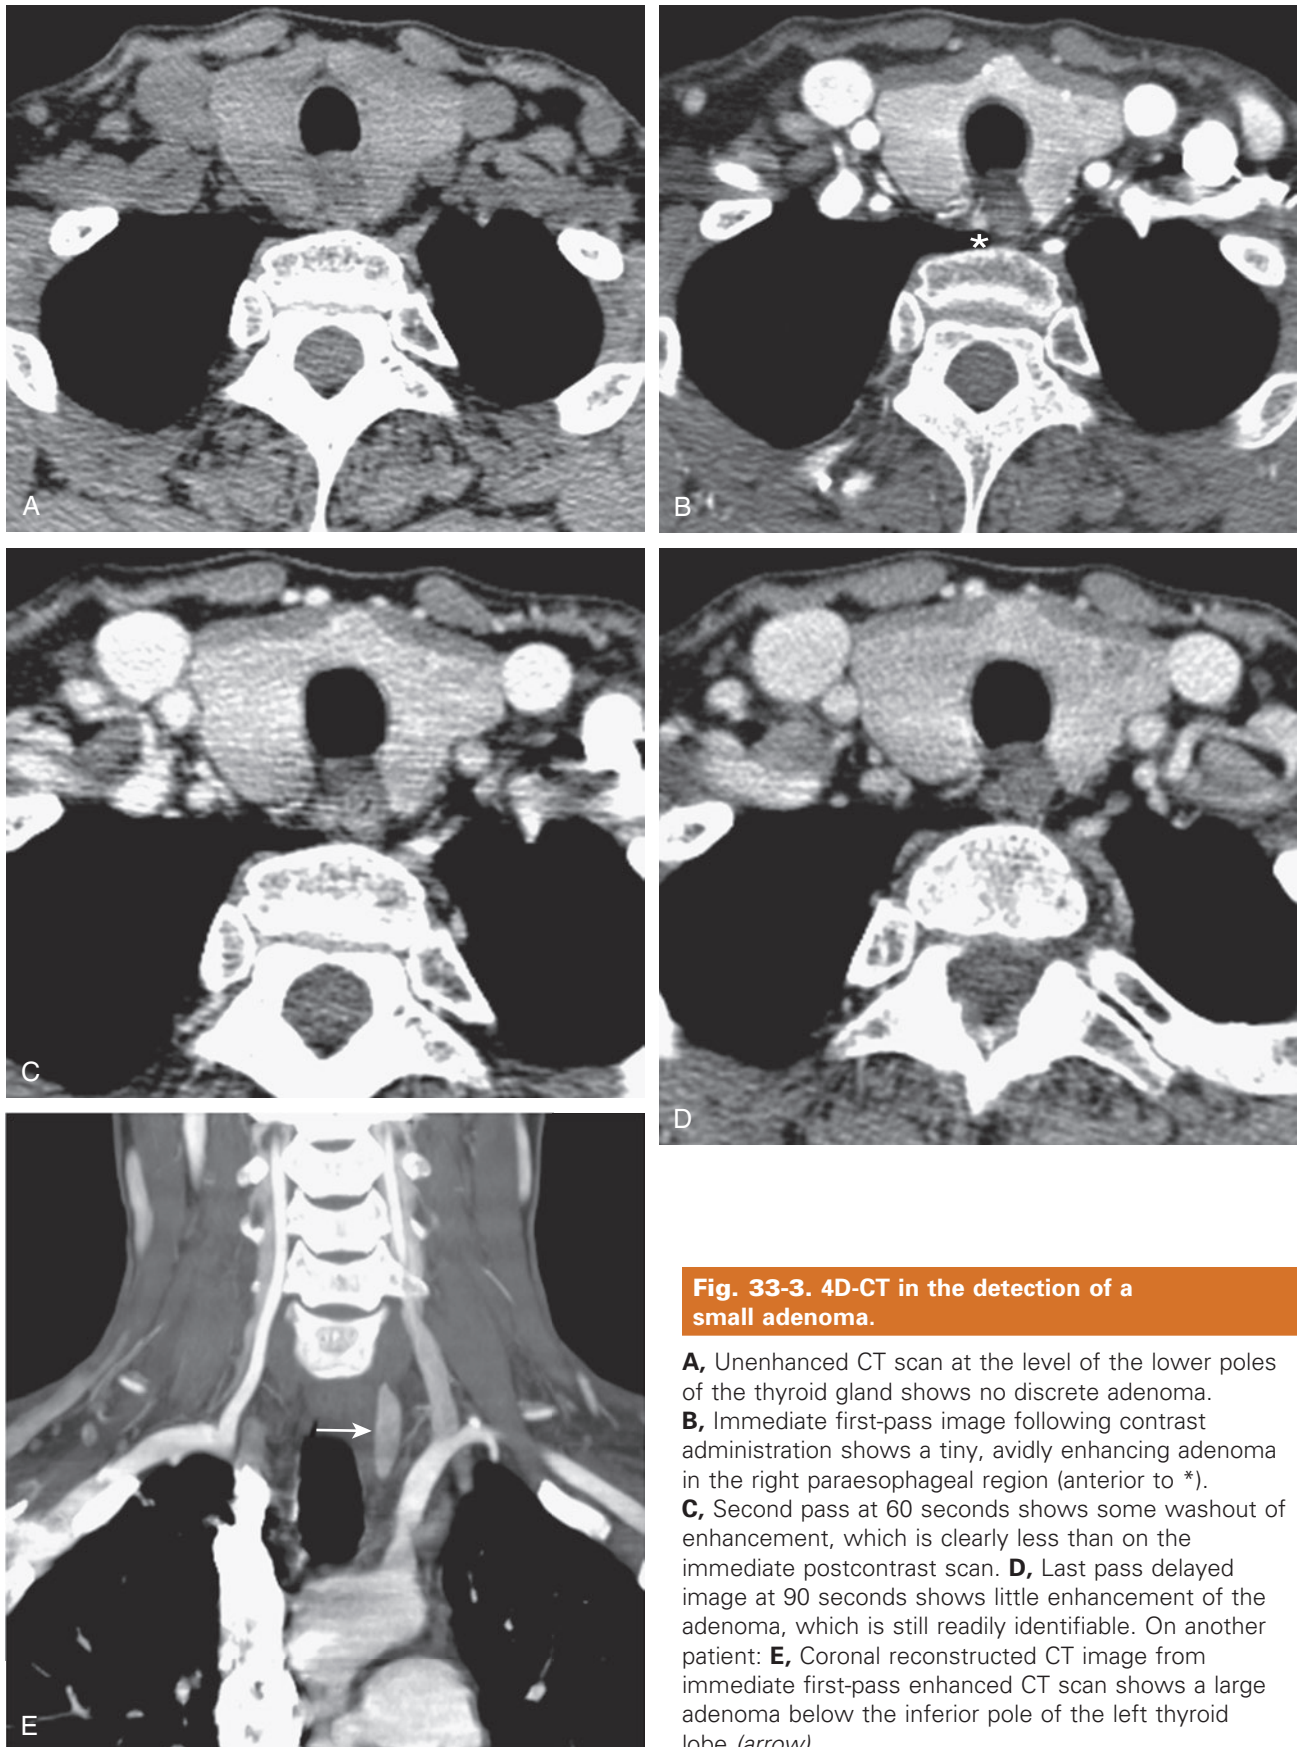

Fig. 33-3. 4D-CT in the detection of a small adenoma.

A, Unenhanced CT scan at the level of the lower poles of the thyroid gland shows no discrete adenoma. **B**, Immediate first-pass image following contrast administration shows a tiny, avidly enhancing adenoma in the right paraesophageal region (anterior to *). **C**, Second pass at 60 seconds shows some washout of enhancement, which is clearly less than on the immediate postcontrast scan. **D**, Last pass delayed image at 90 seconds shows little enhancement of the adenoma, which is still readily identifiable. On another patient: **E**, Coronal reconstructed CT image from immediate first-pass enhanced CT scan shows a large adenoma below the inferior pole of the left thyroid lobe (arrow).

Fig. 33-3, cont'd

F, Coronal maximum intensity projection image in anterior projection shows the adenoma (*arrow*). **G**, Coronal maximum intensity projection image in the posterior projection shows the adenoma (*) posterior to the common carotid artery. (Cases courtesy of Dr. Lawrence Ginsberg. From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 41-101, p 2667.)

Fig. 33-4. Parathyroid adenoma.

Parathyroid adenoma appearing as a large encapsulated lesion bulging into the operative field. Adenomas are typically easily dissected free of adjacent structures; difficulty in removing a parathyroid tumor should raise suspicion for a parathyroid carcinoma.

Fig. 33-5. Parathyroid adenoma.

Cut section of a parathyroid adenoma shows a homogeneous, light tan appearance; a delicate inconspicuous capsule is present. A remnant of uninvolved parathyroid tissue is not grossly visible.

Fig. 33-6. Parathyroid adenoma.

Parathyroid adenoma appearing as a nodular focus with cystic change and associated calcification.

- Nuclei of residual normal or atrophic parathyroid gland typically smaller than the nuclei of the adenoma.
- Growth patterns include solid (diffuse) sheets, cords, nests, acini, follicles, and microcysts:
 - Follicle formation may contain eosinophilic “colloid-like” material.
 - Distinct trabecular pattern is uncommon.
- Predominantly composed of chief cells:
 - Nuclei round and regular with central to slightly basal location within the cell and have inconspicuous nucleoli; usually lack significant pleomorphism:
 - Cells with hyperchromatic enlarged nuclei as well as multinucleated cells are common and can be found scattered throughout the tumor or may be clustered in small foci; these scattered atypical nuclei are not an indicator of malignancy in the absence of other evidence of a malignancy (see section on [parathyroid carcinoma](#)).
 - Cytoplasm varies, including slightly eosinophilic, amphophilic, clear, or oxyphilic.
 - Chief cells of an adenoma frequently larger than the non-neoplastic chief cells in the uninvolved rim of parathyroid tissue, if one is present
 - Oncocytic cells may be seen in variable numbers, focally admixed with chief cells or as nodular aggregates.
- Mitotic figures are identifiable in many adenomas, but usually number fewer than 1 per 10 high-power fields; mitotic rates as high as 4 mitoses per 10 high-power fields have been described in occasional cases.
- Delicate vascular network composed of thin fibrovascular stroma, sinusoid-like blood vessels or capillaries traverse the neoplasm.

Fig. 33-7. Parathyroid adenoma, fine-needle aspiration.

A, Cellular smear with cohesive groups of small epithelial cells and fragments of pink colloid-like material may suggest a follicular neoplasm of thyroid origin; the colloid-like material, however, is somewhat sparse (Diff-Quick stain). **B**, The cells are fragile, yielding smears with numerous naked nuclei, some of which are large and hyperchromatic; scattered large atypical nuclei are common in parathyroid adenomas (Diff-Quick). **C**, Papanicolaou-stained smear shows scattered compact clusters of small epithelial cells with distinct cell borders and a rim of clear cytoplasm; the nuclei are small and hyperchromatic.

Fig. 33-8. Parathyroid adenoma.

A, Parathyroid adenoma characterized by hypercellular proliferation devoid of intraparenchymal fat, which in the lower portion of the illustration has a well-defined capsule separating the cellular proliferation from a thin rim of compressed normal parathyroid gland parenchyma. **B,** At higher magnification, the cells and nuclei of the adenoma (*bottom*) are larger than those of the residual non-neoplastic parathyroid gland parenchyma (*top*).

- Intraparenchymal fat cells absent but may focally be seen as single cells or groups in the peripheral aspect of the neoplasm:
 - Neoplastic cells usually have less intracellular fat than do the cells in the uninvolved (or suppressed) parathyroid tissue, either in other glands or in a rim of non-neoplastic parathyroid tissue in an adenomatous gland.
- Cells with markedly enlarged and hyperchromatic pleomorphic or bizarre-appearing nuclei may be present and when present:
 - Appear admixed with bland-appearing nuclei.
 - Tend to be focally and not diffusely identified.
 - Occur in the absence of increased mitotic activity and/or other features that may be associated with parathyroid carcinoma.

Fig. 33-9. Parathyroid adenoma.

A, Diffuse proliferation of chief cells with scattered admixed oncocytic cells. **B,** Tumor is traversed by delicate fibrovascular stroma.

- Reactive and degenerative changes may be present, including cyst formation, edema, fibrosis, hemorrhage (fresh or in the form of hemosiderin deposition), or infarction:
 - May occur spontaneously or may occur following a traumatic event such as prior surgery to the neck or fine-needle aspiration biopsy
 - Presence of reactive and degenerative changes, especially fibrosis, may cause adherence to adjacent structures, suggesting invasive growth and a possible diagnosis of parathyroid carcinoma.
 - Infarcted tumor may retain antigenicity for parathyroid hormone.
- Rarely, an associated mature lymphocytic cell infiltrate may be present.
- Uninvolved parathyroid parenchymal cells in patients with adenomas are typically smaller and often have more stromal fat cells than the glands in patients

Fig. 33-10. Parathyroid adenoma.

Parathyroid adenomas may be composed of an admixture of (A) chief cells, (B) oncocytic cells, and/or (C) clear cells. In any given tumor two or all of the cell types may be present, creating a mosaic pattern.

Fig. 33-11. IHC staining in parathyroid adenoma.

Lesional cells of parathyroid adenomas are immunoreactive for (A) parathyroid hormone and (B) parafibromin (diffuse nuclear staining).

Fig. 33-12. Parathyroid adenoma.

Parathyroid adenoma showing cord-like or trabecular growth composed of cells with clear-appearing cytoplasm.

Fig. 33-13. Parathyroid adenoma.

A, Parathyroid adenoma showing a follicular pattern of growth (so-called follicular variant) that may cause confusion with thyroid follicular neoplasms; immunoreactivity for **(B)** parathyroid hormone and **(C)** parafibromin (nuclear), coupled to the absence of thyroglobulin and TTF1 (not shown) allow for differentiating parathyroid adenoma from a thyroid follicular lesion.

Fig. 33-14.

A, Parathyroid adenoma composed of uniform and bland-appearing nuclei in lower portion of image as well as numerous large cells with hyperchromatic nuclei; intralesional fibrosis is also present. **B**, Bizarre-appearing pleomorphic and hyperchromatic nuclei admixed with bland-appearing nuclei. Such findings in the absence of increased mitotic activity and/or other features associated with parathyroid carcinoma can be seen in parathyroid adenomas.

without hyperparathyroidism; they also have more cytoplasmic fat, often found as large droplets, than normally functioning parathyroid glands.

- Histochemical stains:
 - Colloid-like material in follicular structures are PAS positive.
 - Considerable variation in the literature regarding the utility of fat stains in the diagnosis of parathyroid proliferative diseases
 - Generally, hyperfunctioning cells have a significantly decreased amount of intracellular fat (using Sudan black or oil red O) compared with

Fig. 33-15. Parathyroid adenoma.

Parathyroid adenoma with associated reactive and degenerative changes, including fibrosis and hemorrhage may result in adherence to surrounding structures, clinically suggesting a possible diagnosis of parathyroid carcinoma. Such changes may occur spontaneously or may occur following a traumatic event such as prior surgery to the neck or fine-needle aspiration biopsy.

normal or suppressed parenchymal cells; there is, however, variability in this finding.

- Fat stains, when used with adequate clinical information, intraoperative findings, and histologic examination, are useful if their limitations are kept in mind.
- Immunohistochemistry:
 - Positive for parathyroid hormone and parafibromin (nuclear staining):
 - Majority of parathyroid adenomas express parafibromin
 - Loss of parafibromin expression may be seen in patients with hyperparathyroidism-jaw tumor syndrome indicative of gene inactivation through mutation of the *HRPT-2* gene.
 - Cytokeratin, chromogranin A positive
 - Calcitonin and synaptophysin typically negative but in small percentage of cases may be focally positive
 - PAX8 (nuclear) reactivity present in approximately 40% of adenomas and hyperplasia
 - Galectin 3 rarely positive (< 5%).
 - Ki67 (MIB1) proliferative index is low:
 - An index greater than 5% should raise suspicion for carcinoma, but the diagnosis of carcinoma requires confirmatory diagnostic findings.
 - Proliferative indices in differentiating adenoma from carcinoma are of limited utility given overlapping findings in these lesions.

Fig. 33-16. Parathyroid adenoma.

A, Parathyroid adenoma with infarction but retention of ghost outlines of the neoplasm. Note the residual noninfarcted and non-neoplastic parathyroid parenchyma, including mature fat (*upper right*). **B**, Parathyroid hormone immunoreactivity is present in the infarcted tumor and in the residual non-neoplastic parathyroid parenchyma (*upper right*).

- Cyclin D1 staining in 39% of cases
- Negative for thyroglobulin and TTF-1
- Electron microscopy:
 - Adenomas associated with very high serum calcium levels may have a large number of microvilli, which are thought to reflect a higher level of endocrine activity
 - Adenomas often have more abundant rough endoplasmic reticulum and more prominent Golgi apparatus than non-neoplastic cells.
 - Annulate lamellae may be seen.
- Cytogenetic and molecular findings:
 - Approximately 5% show pericentric inversion of chromosome 11, causing translocation of cyclin

Fig. 33-17. Intrathyroidal parathyroid adenoma.

A, Intrathyroidal parathyroid adenoma (*lower*) predominantly composed of chief cells as well as oncocytic cells (*arrow*) and clear cells (*arrowhead*) surrounded by thyroid follicular epithelial cells and an adenomatoid nodule (*upper right*). **B**, Histologically, the intrathyroidal parathyroid adenoma shows typical morphologic findings predominantly composed of chief cells and sharply separated from the colloid-filled thyroid follicles (*left side*).

D1 (*CCND-1/PRAD-1*) gene with parathyroid hormone gene, resulting in overexpression of cyclin D1.

- Somatic mutation in *MEN-1* gene at 11q13 in 40% of cases
- Absence of *RET* mutation
- 5% have somatic mutation in *CDKN1B* gene (p27Kip1)

Double Parathyroid Adenomas

- Most “multiple adenomas” represent cases of asymmetric or nodular hyperplasia:

Fig. 33-18. Oncocytic parathyroid adenoma.

A, The tumor is encapsulated and (**B**) exclusively composed of cells with granular eosinophilic-appearing cytoplasm.

- Distinction between hyperplasia and adenoma may be extremely difficult and requires the pathologic examination of more than a single gland.
- Diagnostic criteria for double adenomas include:
 - 2 enlarged, hypercellular parathyroid glands
 - Intraoperative confirmation that remaining parathyroid glands are normal and/or biopsy proven histologically normal parathyroid glands
 - Absence of family history of MEN or familial hyperparathyroidism
 - Permanent cure of hypercalcemia following excision of enlarged glands:
 - Arguably the most definitive criterion
 - Requires years of follow-up to include monitoring of serum calcium and parathyroid hormone levels

Fig. 33-19. Parathyroid lipoadenoma.

Lipoadenomas form cords, islands, and follicles admixed with stromal fat cells with mature adipocytes, the latter making up from 20% to 90% of the neoplasm. Lipoadenomas are encapsulated and may be associated with a rim of “normal” gland (not shown) and can be difficult to distinguish from normal parathyroid gland in small biopsies.

Fig. 33-20. Parathyroid adenoma associated with osteitis fibrosa cystica.

Left panel, The adenoma is typical with a distinct capsule and a rim of normal parathyroid parenchyma including mature fat (lower); *right panel*, the tumor is composed of chief cells. The patient had a pathologic fracture of the humerus as well as generalized osteopenia with multiple lytic skeletal lesions. At the time of presentation he had hypercalcemia. The initial clinical impression was metastatic carcinoma with secondary hypercalcemia.

- If the above criteria are fulfilled, then a diagnosis of double adenomas can be confirmed.
- True double parathyroid adenomas are rare:
 - Majority (greater than 70%) are bilateral
 - Predilects to superior glands

Fig. 33-21. Brown tumor of hyperparathyroidism.

The humeral lesion from the patient in Fig. 33-20. *Left panel*, Dissecting osteitis, with resorption of trabecular bone and replacement by fibrous tissue; the presence of hemosiderin indicates hemorrhage secondary to microfractures in the weakened bone. *Right panel*, Brown tumor of hyperparathyroidism develops after repeated cycles of bone resorption, microfractures, and hemorrhage, leading to large areas of cystic degeneration with aggregates of osteoclasts and foreign body giant cells in a fibroblastic stroma containing hemosiderin.

Histologic Variants of Parathyroid Adenoma

- Oncocytic (oxyphilic) adenoma (see Fig. 33-18):
 - Exclusively composed of oncocytic cells with prominent eosinophilic granular cytoplasm
 - Demographic features are similar to those of the more common adenomas composed of chief cells
 - Thought to be nonfunctional; usually associated with lesser degree of hypercalcemia; however, several reports document an association with primary hyperparathyroidism
 - Composed of large cells with abundant eosinophilic granular cytoplasm and hyperchromatic nuclei:
 - Scattered large atypical nuclei or multinucleated cells may be seen.
 - Cytoplasm is stuffed with mitochondria on electron microscopy.
 - An important differential consideration is the frequent presence of nodular oncocytic cell change seen in normal glands with increasing age.
 - Intrathyroidal localization may suggest a diagnosis of an oncocytic thyroid follicular (so-called Hürthle cell) neoplasm:
 - Parathyroid oncocytic adenomas have more distinct cell membranes.

Fig. 33-22. Brown tumor of hyperparathyroidism.

Brown tumor of hyperparathyroidism characterized by (A) proliferation of numerous multinucleated giant cells and mononuclear cells, as well as foci of hemorrhage; the giant cells tend to be clustered rather than diffusely distributed. B, The nuclei of the multinucleated giant cells are rather bland and are similar to those of the surrounding mononuclear cells. A mitotic figure (arrow) is present. The brown tumor of hyperparathyroidism is histologically similar to giant cell (reparative) granuloma, thereby requiring clinical and laboratory correlation to differentiate these lesions.

- Presence of thyroglobulin and TTF1 support lesion of thyroid origin.
- Lipoadenoma (see Fig. 33-19)
 - Also referred to as parathyroid hamartoma
 - Rare benign neoplasm characterized by proliferation of chief and oxyphilic cells forming cords, islands, and follicles admixed with mature adipocytes:
 - Mature adipocytes make up from 20% to 90% of the neoplasm.
- Circumscription and/or encapsulation as well as large size (1 to 15 cm) support adenomatous nature:
 - May be associated with a compressed rim of “normal” gland
- May be difficult to recognize as “abnormal” parathyroid tissue in small biopsies, when they are easily mistaken for normal parathyroid tissue because of the abundance of stromal fat
- Stromal fat often contains areas of fibrosis or myxoid alteration.
- Most are associated with hyperparathyroidism.
- Other rare variants of parathyroid adenoma include:
 - Papillary variant characterized by prominent papillary architecture:
 - May not be a “true” variant but papillary architecture, especially in association with fibrosis and hemorrhage (recent and remote), likely is a reactive/degenerative phenomenon
 - Follicular variant characterized by prominent follicular (acinar) architecture
 - Water-clear variant characterized by presence of polygonal cells with clear cytoplasm and distinct cell membranes.
- Atypical parathyroid adenoma:
 - Definition: parathyroid tumor showing features worrisome for parathyroid carcinoma but lacking absolute diagnostic features for parathyroid carcinoma
 - Synonyms include atypical parathyroid neoplasm, parathyroid neoplasm of uncertain biologic significance, or parathyroid neoplasm inconclusive for malignancy
 - Atypical histologic features suggesting carcinoma but falling short for this diagnosis may include:
 - Capsular irregularities or invasion without infiltration into adjacent soft tissues
 - Increased mitotic activity (>5 per 10 high-power fields)
 - Intralesional fibrosis characterized by broad fibrous bands coursing through the lesion
 - Coagulative necrosis
 - Diffuse cellular atypia
 - Diffuse sheet-like growth of monotonous cells with increased nuclear-to-cytoplasmic ratio
 - Macronucleoli in many cells
 - Atypical parathyroid adenomas lack conclusive features diagnostic for carcinoma including:
 - Invasion of surrounding soft tissues
 - Invasion of surrounding structures including thyroid gland, larynx, trachea, pharynx, esophagus, carotid artery, recurrent laryngeal nerves
 - Angioinvasion
 - Perineural invasion
 - Metastasis

TABLE 33-1 Comparative Features of Parathyroid Proliferative Diseases

	Hyperplasia	Adenoma	Carcinoma
Gender; age	Slight female predilection; most common in 5th-6th decades	More common in women; most common in 4th decade	Equal gender predilection; wide age range
Clinical	Asymptomatic or complaints of lethargy, weakness, polyuria, polydipsia, arthralgia, constipation, and depression	Similar to hyperplasia	Similar to hyperparathyroidism of benign cause but more severe due to the higher serum calcium levels; higher proportion of renal disease (nephrolithiasis) and bone disease; peptic ulcer disease; palpable neck mass more common than in adenoma
Serum calcium	11.7 mg/dl (average)	12.5-13.5 mg/dl	Often >14 mg/dl
Intraoperative findings	2 or more glands enlarged, easily dissected; enlargement may be very asymmetric	1 gland enlarged; easily dissected; more frequent in lower glands or ectopic sites	1 gland enlarged; often adherent to surrounding tissues
Weight	Total gland weight usually <1 g, but may be up to 5 g	0.3-1.0 g commonly, but may weigh several grams in patients with bone disease	>1.5 g (often much larger)
Capsule	Circumscribed by capsule of parathyroid gland, may be incomplete. No compressed rim of atrophic or normal parathyroid tissue	Thin tumor capsule, often surrounded by rim of uninvolved parathyroid, which may appear atrophic	Thickened capsule; rim of normal parathyroid rarely seen
Gross appearance	Gray-brown, soft. Cut surface may be homogeneous or nodular. Lacks fibrous bands	Red-brown, firm. Usually homogeneous, lacks fibrous bands	Gray-white, firm, often lobulated or irregular. Fibrous bands often produce coarse nodularity
Histologic pattern	Diffuse or nodular, sometimes pseudofollicular or acinar	Diffuse or nodular, frequently pseudofollicular or acinar	Diffuse, nodular, pseudofollicular, or acinar; often trabecular pattern with distinctive nuclear palisading predominates
Cytologic features	Chief cells predominate; transitional and oncocytic cells often present	Chief cells predominate, but mixture of chief, transitional, and oncocytic cells may be seen; rarely, purely oncocytic	Cells usually resemble chief cells, but variable cytoplasmic oncocytic change may be seen; cell borders often indistinct
Intracytoplasmic lipid	Decreased	Decreased in tumor; abundant in atrophic rim of parathyroid	Usually absent
Stromal fat cells	Scanty to absent	Usually absent in tumor; present rim of atrophic parathyroid	Absent
Nuclear morphology	Normal to slightly increased N-to-C ratio; usually without nuclear pleomorphism	Nuclei enlarged, with variability in size; scattered groups of large pleomorphic, hyperchromatic nuclei, or multinucleated cells	Increased N-to-C ratio; enlarged atypical nuclei; often with monotonous (bland appearing) nuclei
Nucleoli	Inconspicuous to small	Inconspicuous to small	Frequently prominent and enlarged
Mitoses	Common (60% of cases; most with <1 mitotic figure/10 HPF)	Common (70% of cases; most with <1 mitotic figure/10 HPF)	Common (80% of cases), may include atypical mitoses; may be numerous

Continued

TABLE 33-1 Comparative Features of Parathyroid Proliferative Diseases—cont'd

	Hyperplasia	Adenoma	Carcinoma
Capsular and vascular invasion	Absent	Absent; entrapment of tumor cells may occur in capsule if degenerative changes present	Capsular invasion present in two thirds; may involve only capsule or extend into adjacent tissues Vascular invasion present in up to 15%; usually in capsular vessels
Remainder of gland	Entire gland is abnormal	Normal or atrophic	Normal
Degenerative changes	May be seen in very large glands Includes hemorrhage, areas of fibrosis, and cystic change	Common, especially in larger adenomas; includes hemorrhage, fibrosis, and cystic change, sometimes calcification	Tumor cell necrosis; calcification and cystic changes may be present
Treatment	Subtotal parathyroidectomy with surgical removal of three glands, leaving a remnant of the 4th or total parathyroidectomy* with autotransplantation of parathyroid tissue in forearm	Surgical removal of the enlarged gland	En bloc resection, including ipsilateral thyroid lobe and adjacent soft tissues
Prognosis	Excellent	Excellent	Up to 50% of patients are cured by en bloc resection; considered an indolent malignancy even in presence of recurrence or metastasis with long survival even after recognition of tumor recurrence; morbidity and mortality correlate to complications of severe hypercalcemia
Recurrence and metastasis	Recurrence in approximately 16% of cases due to inadequate neck exploration and may not be evident for years	Absent	Recurrence in two thirds of patients usually within 3 years of the first surgery; metastasis is 35%, is a late event usually preceded by local recurrence; most commonly to lung, cervical lymph nodes, and liver
Familial and/or MEN association	Yes, in approximately 20% of cases	Uncommon	Rare

g, Grams; HPF, high power fields; MEN, multiple endocrine neoplasia syndrome; N-to-C, nuclear-to-cytoplasmic.

*Particularly in cases of familial hyperparathyroidism.

- Most atypical parathyroid adenomas prove to be benign in long-term follow-up, but owing to the uncertainty in their malignant potential, they have been termed atypical.
- Treatment is similar to a typical parathyroid adenoma, but patients should be followed for potential recurrent hyperparathyroidism, local recurrence of tumor, and/or evidence of aggressive behavior (e.g., metastasis).

Differential Diagnosis

- Primary chief cell hyperplasia (see Table 33-1)
- Parathyroid carcinoma (see Table 33-1)
- Follicular neoplasm of thyroid gland

Treatment and Prognosis

- Most widely accepted therapy is excision of the adenomatous gland with biopsy of at least one additional gland that is “normal” in size

- Some favor a full bilateral neck exploration with subtotal parathyroidectomy and have reported a lower incidence of recurrent hypercalcemia that required reoperation:
 - There is an increased incidence of postoperative hypoparathyroidism with this procedure.
- Recurrence rates vary significantly and may reflect problems in classification, particularly in cases of hyperplasia with nodules, which may erroneously be designated as adenomas.
- Although generalized osteopenia is now more common, osteitis fibrosa cystica, also known as brown tumor of hyperparathyroidism is occasionally seen (see Figs. 33-20 to 33-22):
 - May occur in hyperparathyroidism of any cause but is related to degree and duration of serum calcium elevation
 - Lesions are characterized by resorption of bone, which is replaced by fibrous tissue, probably as a reparative response to microfractures
 - Hemorrhage within the fibrous tissue leads to the accumulation of hemosiderin and a proliferation of multinucleated giant cells in addition to the osteoclasts
 - With time degenerative changes lead to the formation of cystic spaces
 - Osteitis fibrosa cystica cannot be distinguished histologically from the giant cell (reparative) granuloma of the jaw; clinical information is essential.
- Recurrent hyperparathyroidism following surgery for an adenoma may also result from incomplete excision, rupture of the tumor capsule with spillage into the operative field, or from hyperfunction of autografted parathyroid tissue following subtotal parathyroidectomy.

PARATHYROID CARCINOMA

(Figs. 33-23 through 33-38,
see Table 33-1)

Definition: Malignant neoplasm of parathyroid parenchymal cells.

Clinical

- Rare neoplasm; responsible for approximately 2% of cases of hyperparathyroidism
- No gender predilection; most common in fifth and sixth decades:
 - Affect patients approximately a decade younger than those with adenomas
 - Rare cases reported in children
- Clinical findings associated with parathyroid carcinoma are listed in Box 33-2.

BOX 33-2 Clinical Features Associated with Malignancy in Parathyroid Neoplasms

- Serum calcium level >14 mg/dl
 - Serum parathormone levels 2 to 3 times normal
 - Severe metabolic manifestations: nephrolithiasis, bone disease, etc.
 - Palpable neck mass
 - Difficulty in surgical dissection owing to adherence to surrounding structures
- Most patients have severe hypercalcemia and hypophosphatemia:
 - Mean serum calcium 14.0 mg/dl, in contrast to mean serum calcium of 12.0 mg/dl in benign hyperparathyroidism
 - Occasional normocalcemic patients may occur.
 - Symptoms are due to excessive parathyroid hormone secretion and are similar to those in patients with hyperparathyroidism of benign cause but tend to be more severe due to the higher serum calcium levels:
 - Presenting symptoms include polyuria, polydipsia, fatigue and weakness, depression, bone pain and fracture (high incidence in earlier series), renal colic and nephrolithiasis (up to two thirds of patients in earlier studies, but probably decreasing with routine biochemical screening and earlier detection), peptic ulcer disease, and recurrent pancreatitis.
 - Palpable neck masses more common than in hyperplasia or adenoma.
 - Etiology is unknown:
 - Most cases are sporadic.
 - Loss of the retinoblastoma (Rb) tumor-suppressor gene may play an important role in the development of parathyroid carcinoma, and its absence may be helpful in distinguishing parathyroid adenoma from carcinoma.
 - Some cases occur in hyperparathyroidism-jaw tumor syndrome, MEN, or familial isolated hyperparathyroidism.
 - External beam irradiation to the neck may be a possible risk factor.
 - Rare cases occur in patients with secondary hyperparathyroidism, possibly linking the development of parathyroid carcinoma from parathyroid adenoma or hyperplasia.
 - May be associated with hyperparathyroidism-jaw tumor syndrome (HPT-JT):
 - Autosomal-dominant disorder with germline mutation in *HRPT-2* gene on chromosome 1q25-31
 - Characterized by:
 - Parathyroid adenoma or carcinoma
 - Fibro-osseous lesions of the jaw (e.g., ossifying fibroma of mandible or maxilla): 30% of cases

Fig. 33-23. Parathyroid carcinoma in a patient with severe hyperparathyroidism.

A, Axial T2-weighted MR image shows a demarcated 2.5-cm mediastinal mass (*) that represents a parathyroid carcinoma. **B**, Axial T2-weighted MR image of another patient with hypercalcemia shows a nonhomogeneous mass in the right tracheoesophageal groove. The margins are slightly unsharp. This is a parathyroid carcinoma. **C**, Axial T2-weighted MR image shows a large mass in the right tracheoesophageal groove in this patient with severe hypercalcemia. At surgery, this was a parathyroid carcinoma. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 41-110, p 2674.)

- Renal cyst, hamartoma, carcinoma: 20% of cases
- Approximately 80% of patients develop hyperparathyroidism.
- Usually presents late in adolescence
- Hypercalcemia tends to be severe.
- Higher incidence of parathyroid carcinoma in comparison with patients with MEN-1 and MEN-2A
 - Renal lesions may include:
 - Renal cysts, polycystic renal disease, renal hamartoma
 - Papillary renal cell carcinoma, renal cortical adenomas, Wilms tumor

Radiology

- Imaging procedures are of similar utility as in parathyroid adenomas.

Fig. 33-24. Parathyroid carcinoma.

Parathyroid carcinoma appearing as a large tumor with areas of cystic degeneration associated with large nodules of viable tumor; the capsule is grossly thickened.

Fig. 33-25. Parathyroid carcinoma.

Parathyroid carcinoma appearing as an irregular, infiltrative, indurated, white neoplasm adherent to the adjacent thyroid lobe (*on the left*). Difficulties in dissection a parathyroid lesion from adjacent structures is suggestive, although not definitively diagnostic, for carcinoma. Histologic confirmation is always required for a diagnosis of parathyroid carcinoma.

Pathology

- Pathologic findings potentially associated with parathyroid carcinoma are listed in [Table 33-2](#).

Gross

- Average size is larger than parathyroid adenomas: mean weight 6.7 g (range 1.5 to 27 g), although smaller tumors are being identified more often in recent years.
- May be encapsulated or infiltrative

Fig. 33-26. Parathyroid carcinoma.

Some parathyroid carcinomas like this one are more advanced at presentation with extensive invasion of surrounding tissues. Cases such as this one are rare today as a result of routine biochemical screening of most populations in developed countries.

Fig. 33-27. Parathyroid carcinoma.

Parathyroid carcinoma characterized by a thickened capsule, and fibrous bands dissecting through the tumor dividing the tumor into separate nodules; the tumor was adherent to and invaded into the thyroid gland (*right*).

- Brown to gray-white, carcinomas may have a smooth, firm cut surface indistinguishable from an adenoma or may be distinctly indurated
- Difficulty in dissection of the tumor and adherence to the thyroid gland are common intraoperative observations.

Histology

- Histologic criteria in diagnosing parathyroid carcinoma are detailed in [Table 33-2](#).
- Many parathyroid carcinomas are encapsulated, and usually the capsule of a carcinoma is thicker than that seen in most adenomas:
 - Some adenomas with reactive and degenerative changes have thick and uneven capsules.

Fig. 33-28. Parathyroid carcinoma.

Parathyroid carcinoma with acellular fibrous bands coursing through the neoplasm dividing the tumor into multiple nodules.

Fig. 33-30. Parathyroid carcinoma.

Parathyroid carcinoma (*P*) with perineural invasion (*arrows*). The neoplastic proliferation includes rather bland-appearing and uniform nuclei, but the presence of neurotropism represents invasive growth diagnostic for carcinoma.

Fig. 33-29. Parathyroid carcinoma.

Parathyroid carcinoma showing vascular invasion within an endothelial-lined blood vessel.

Fig. 33-31. Parathyroid carcinoma.

Parathyroid carcinoma characterized by hypercellularity and trabecular growth.

TABLE 33-2 Pathologic Features Associated with Malignancy in Parathyroid Neoplasms

Features Definitively Diagnostic for Malignancy	Features Worrisome for But Not Definitively Diagnostic for Malignancy
<ul style="list-style-type: none"> • Invasive growth including into: <ul style="list-style-type: none"> Surrounding soft tissues Surrounding viscera or vital structures (thyroid gland, larynx, trachea, esophagus, pharynx, carotid artery, recurrent laryngeal nerve) • Vascular invasion • Perineural invasion • Metastatic disease: <ul style="list-style-type: none"> Regional lymph nodes Distant sites 	<ul style="list-style-type: none"> • Large size (mean weight 6.7 g) • Adherence to surrounding structures (e.g., thyroid tissue, others) • Irregular contour; lack of distinct encapsulation • Thick capsule • Intralesional fibrous bands • Mitotic activity (especially >5 per 10 HPF) • Coagulative tumor necrosis • Diffuse cellular atypia • Diffuse sheet-like monotonous small cells with increased N:C • Macronucleoli in many tumor cells • Trabecular growth • Spindling of tumor cells

Fig. 33-32. Parathyroid carcinoma.

Higher magnification of the previous illustration shows the trabecular pattern of growth composed of fairly uniform, monotonous-appearing nuclei, although scattered enlarged (pleomorphic) nuclei are present. Such enlarged atypical nuclei can be seen in adenomas, and by itself is not a definitive diagnostic feature for carcinoma. Such enlarged atypical nuclei are considered to be an uncommon feature in parathyroid hyperplasia.

Fig. 33-33. Parathyroid carcinoma.

A comparison of the nuclei in parathyroid carcinoma (*left*) with parathyroid adenoma (*right*) shows the cells of the carcinoma to have a higher nuclear-to-cytoplasmic ratio than those of the adenoma. Such a feature is worrisome but in the absence of other findings is not diagnostic for carcinoma.

- Growth patterns also vary and include solid sheets, acinar formation, cords, rosettes, and, of particular differential diagnostic significance, trabecular pattern:
 - Trabecular pattern is a finding more often identified in association with parathyroid carcinoma than in adenoma or hyperplasia, and its presence,

Fig. 33-34. Parathyroid carcinoma.

Parathyroid carcinoma with spindle-shaped tumor cells.

Fig. 33-35. Parathyroid carcinoma with mitotic figure (arrow).

Mitoses are not, by themselves, accurate predictors of malignancy, because they may be seen in parathyroid hyperplasia and adenomas.

even focally, should raise suspicion for the diagnosis of carcinoma.

- Nuclear palisading may be prominent in trabecular areas.
- Spindling of cells is also a feature more often seen in carcinomas than in benign proliferations.
- Trabecular pattern and spindle-shaped cells, although worrisome for a possible diagnosis of carcinoma, are not definitive diagnostic features for carcinoma.

Fig. 33-36. Parathyroid carcinoma with necrosis.

Fig. 33-37. Parathyroid carcinoma.

Parathyroid carcinoma showing markedly enlarged and hyperchromatic nuclei; although similar nuclear atypia can be seen in adenomas, the fact that these changes were diffusely present rather than focally present (as single atypical nuclei and/or in small clusters within the tumor) supports a diagnosis of parathyroid carcinoma and not parathyroid adenoma or hyperplasia. A monotonous nuclear pattern is, surprisingly, more often seen in carcinomas than in adenomas.

- Follicular pattern of growth not often if ever seen in parathyroid carcinomas
- Tumor cells may have variable morphology:
 - Some areas may show similar features as benign chief cells with slightly eosinophilic to clear cytoplasm.
 - Other areas may contain enlarged cells with more distinctly eosinophilic cytoplasm, large nuclei with prominent nucleoli.
 - Rare oncocytic cell variant identified.

Fig. 33-38. Parathyroid carcinoma.

Parathyroid carcinoma characterized by a monotonous but crowded proliferation of cells with large nuclei and very large eosinophilic nucleoli (macronucleoli); these findings seen in some parathyroid carcinomas are not typically present in benign parathyroid lesions (i.e., adenoma, hyperplasia); mitotic figures can be seen (*middle upper, upper right*).

- Nuclear pleomorphism is less common than in adenomas, which often contain scattered foci with enlarged atypical nuclei:
 - Monotony of nuclear size and shape is frequently present in carcinomas.
 - Pleomorphism, when present, is usually more diffuse than in adenomas.
- Mitotic activity is identified in most, but not all, parathyroid carcinomas:
 - Presence of atypical mitoses is virtually diagnostic of malignancy
 - Although a high mitotic rate is a helpful feature, the presence of mitotic activity exceeding 1 per 10 high-power fields in a minority of parathyroid adenomas and in parathyroid hyperplasia may be seen.
 - Overlap in mitotic activity between all parathyroid proliferative diseases (i.e., adenoma, hyperplasia, and carcinoma) makes mitotic activity a useful finding only when coupled with other features of malignancy.
- Capsular invasion may be obvious in some cases, or may be represented only by irregular tongues or islands of parathyroid tissue protruding into the capsule; invasion beyond the capsule is indicative of malignancy:
 - Entrapped islands of parathyroid parenchymal cells in benign disease should be distinguished from these invasive foci by their rounded contours and lack of desmoplastic reaction.

- Fibrous bands extending from a thickened capsule frequently divide the tumor into irregular compartments and/or nodules.
- Angioinvasion is diagnostic of carcinoma but is present in a minority of cases:
 - Usually found within vessels in the thick tumor capsule
 - Artfactually displaced clumps of tumor cells in vascular spaces should be distinguished from true invasion by their frequently degenerated appearance and by their lack of attachment to the vessel wall.
- Perineural invasion, although rarely seen, is also virtually diagnostic of malignancy.
- Immunohistochemistry:
 - Positive for cytokeratins, chromogranin as well as for parathyroid hormone
 - Loss of (nuclear) parafibromin staining is common but not invariably identified:
 - Only about 50% of carcinomas lack parafibromin staining
 - Some carcinomas may show positive parafibromin staining
 - Loss of parafibromin reported in sporadic adenomas (unassociated with hyperparathyroidism-jaw tumor syndrome)
 - High frequency of cyclin D1 expression (reported in more than 90% of cases):
 - May result from loss of parafibromin expression
 - May reflect increased cellular proliferation
 - High levels of expression also present in hyperplasia (approximately 61%) and adenomas (approximately 39%) so not uniquely seen in carcinoma.
 - Galectin-3 reactivity frequently seen:
 - More than 90% of cases reported positive
 - Seen in less than 5% of parathyroid adenomas
 - Diffuse strong staining for protein gene product 9.5 (PGP9.5) frequently found
 - Ki67 (MIB1) proliferative index may be increased:
 - An index greater than 5% should raise suspicion for carcinoma but the diagnosis of carcinoma requires confirmatory diagnostic findings.
 - Proliferative indices in differentiating adenoma from carcinoma are of limited utility given overlapping findings in these lesions.
 - Loss of immunoreactivity for retinoblastoma (Rb) protein
 - Negative for thyroglobulin and TTF-1
- Cytogenetic and molecular biology:
 - Mutations of tumor suppressor gene *HRPT-2* may be important in the pathogenesis of parathyroid carcinoma:
 - Inactivation of germ line mutations in *HRPT-2* believed to play a significant role in the development of parathyroid carcinoma
 - Located on 1q25
 - Encodes parafibromin known to function in the suppression of cyclin D1
 - Implicated in the hyperparathyroidism-jaw tumor syndrome
 - Identified in two thirds of cases of sporadic occurring parathyroid carcinoma
 - Practically never found in parathyroid adenomas
 - Allelic loss of the retinoblastoma (Rb) tumor-suppressor gene is common:
 - May play an important role in the development of parathyroid carcinoma
 - Loss of immunoreactivity for Rb protein reported in 20% to 100% of parathyroid carcinomas
 - Absence may be helpful in distinguishing parathyroid adenomas from carcinomas but not considered sufficiently reliable in differentiating adenoma from carcinoma
 - Somatic mutation in *MEN-1* gene:
 - Found in 13% of carcinomas
 - Suggests a role in the development of carcinoma
 - Allelic loss of the p53
 - Reduced expression of cyclin-dependent kinase inhibitor protein p27 commonly identified:
 - In contrast, adenomas show higher labeling index.

Differential Diagnosis

- Parathyroid adenoma (see [Table 33-1](#))
- Parathyroid hyperplasia (see [Table 33-1](#))
- Parathyromatosis:
 - Represents microscopic foci of hyperplastic parathyroid tissue in the soft tissues of the neck in association with primary chief cell hyperplasia
 - May be the cause of recurrent disease after an apparently complete resection of the grossly evident hyperplastic glands
 - Should not be mistaken for invasion as seen in parathyroid carcinoma; differentiating features may include:
 - Absence of associated fibroblastic reaction or infiltrative contour
 - Absence of an intravascular location of these nests
 - Absence of other histologic features of carcinoma should help exclude malignancy.
- Metastatic carcinoma from another site

Treatment and Prognosis

- Surgery is the primary treatment modality with recommended treatment including en bloc resection, to include the ipsilateral thyroid lobe, strap muscles, recurrent laryngeal nerve, trachea, or esophagus if involved:
 - Offers the best chance for cure
 - Up to 50% of patients are cured by en bloc resection.
- Prophylactic lymphadenectomy not recommended due to the low rate of nodal disease (reported to be 6%):
 - Neck dissection warranted if there is clinical evidence of neck (nodal) disease
- Adjuvant radiotherapy may improve local control and limit the occurrence of local relapse, especially when the carcinoma is incompletely excised with involvement of resection margins.
- Efficacy of chemotherapy not proven
- In general, parathyroid carcinomas are generally indolent behaving:
 - 5-year survival from 60% to 85%
 - 10-year survival from 40% to 79%
- Recurrences generally manifest within 3 years of the first surgery with locally recurrent disease:
 - Recurrence rates range from approximately 33% to 50%
 - Lower rates of recurrence reported (8%) with en bloc resection
 - Higher recurrence rates reported (51%) when treated by parathyroid gland excision
- Metastatic disease occurs rather late in the course of disease:
 - Found in approximately one third of patients
 - Usually occurs several years after primary diagnosis
 - Sites of metastases include regional lymph nodes, mediastinum, lungs, liver, and bones.
- Surgical resection of metastatic or locally recurrent disease is frequently helpful due to the rather indolent nature of parathyroid carcinoma:
 - Patients usually survive for several years after recognition of tumor recurrence.
- Recurrence and/or metastatic disease often manifest with recurrent hypercalcemia:
 - Lifelong monitoring for recurrent and/or metastatic disease most effectively accomplished with serum calcium levels.
- Major difficulty in management of recurrent disease is severe hypercalcemia and its complications.
- Death is related to excessive hormonal production with subsequent hypercalcemia rather than directly to tumor burden.
- Prognosis has been shown to be related to tumor stage:

- Stage I: invasion of surrounding soft tissues; 90% disease-free survival
- Stage II: vascular invasion; 46% disease-free survival
- Stage III: invasion of vital organs or regional lymph node metastasis; 50% disease-free survival
- Stage IV: distant metastases; no disease-free survival

SECONDARY NEOPLASMS

(Fig. 33-39)

Definition: Contiguous involvement from tumors in adjacent structures or metastatic neoplasms from distant sites involving the parathyroid gland.

Clinical

- Usually asymptomatic; may present with a neck mass; other symptoms may include hoarseness, dysphagia, and neck pain; rare cases have been associated with clinical hypoparathyroidism due to massive replacement of multiple glands
- May result from direct extension, especially from thyroid or laryngeal tumors, or from metastatic spread
- Metastasis to parathyroid glands is rare; among the more common primary malignancies that may metastasize to the parathyroid glands include:
 - Breast carcinoma (most common)
 - Hematologic malignancies

Fig. 33-39. Metastatic breast carcinoma.

Metastatic breast carcinoma to the parathyroid gland. Residual parathyroid parenchyma is present in the center of the image surrounded by a malignant glandular lesion. The patient had a known history of breast carcinoma that was widely metastatic, including the parathyroid gland. Immunohistochemical staining (not shown) included reactivity for mammaglobin, BRST-2, and GATA-3.

- Malignant melanoma
- Lung carcinoma
- Renal cell carcinoma
- Sarcomas

Pathology

- Found in 11.9% of cancer patients in autopsy studies
- May involve one or multiple glands
- Immunohistochemistry:
 - A variety of organ-specific markers may be helpful in the diagnosis of a metastatic tumor to the parathyroid gland
 - Presence of specific immunomarkers helpful in distinguishing between primary and secondary neoplasms:
 - Breast carcinoma: mammaglobin, BRST2, GATA-3
 - Hematologic malignancies: CD45 (leukocyte common antigen), B-cell (CD20, others), T-cell (CD3, others)
 - Malignant melanoma: S100 protein, HMB45, melan A, tyrosinase, MITF1, Sox10, vimentin

- Lung carcinoma: Napsin A, TTF1
- Renal cell carcinoma: RCC antibody, CD10, PAX2, PAX8, CAIX
- Prostate carcinoma: PSA, PAP, prostatein

Differential Diagnosis

- Parathyroid carcinoma:
 - Reactivity for parathyroid hormone, chromogranin

Treatment and Prognosis

- Treatment based on primary site of origin
- Prognosis poor, related to dissemination of primary disease

Intraoperative Consultation (Frozen Section) in Parathyroid Gland and Parathyroid Proliferative Disease (PPD)/Hyperparathyroidism

CONSIDERATIONS

- Optimal management of primary hyperparathyroidism is achieved by selective removal of parathyroid glands guided by the histologic findings in each gland.
- Surgical management of a patient with primary hyperparathyroidism is to remove one or more enlarged parathyroid glands.
- Pathologists play a primary role in the clinical care of the patient.
- At the time of parathyroid exploration the initial assessment of the excised tissue is the intraoperative histopathologic determination of whether the excised tissue is parathyroid tissue and, if so, whether it is or is not abnormal:
 - In the majority of cases the identification of parathyroid tissue is rather simple, but at times this determination may prove difficult.
 - It is well established that the differentiation of an adenoma from hyperplasia in a single enlarged gland cannot be made by histopathologic evaluation and that detailed clinical information (pre- and postoperative) is required to arrive at the diagnosis.
- The most common developmental anomaly of the parathyroid glands is ectopia, which usually represents a variation in embryologic migratory pattern.
- Parathyroid agenesis is very rare:
 - DiGeorge syndrome includes complete or partial absence of the third and fourth pharyngeal pouches and their derivatives, including the thymus, the parathyroid glands, and thyroid C-cells.
 - Manifests as multiple facial malformations, hypoplasia of the thyroid, hypoparathyroidism, and cardiac abnormalities

NORMAL SIZE AND WEIGHT (Table 34-1)

- The parathyroid glands are soft yellow-brown to dark-brown, circumscribed, ovoid structures; some parathyroid glands are bilobed or flattened.

TABLE 34-1 Comparison of Normal Parathyroid Tissue to Abnormal Parathyroid Tissue

Parameter	Normal Range	Abnormal Changes
Number	Usually 4, sometimes 5	Ectopia
Size	Length 3-6 mm Width 2-4 mm Thickness 0.5-2.0 mm	Enlarged gland greater than 6 mm
Weight	Approximately 0 ± 3.5 mg women; 142 ± 5.2 mg men Approximately 30 mg each: men: 120 ± 5.2 mg women 142 ± 5.2 mg (lower glands usually heavier than upper glands)	Any gland weighing greater than 60 mg
Percentage fat	Approximately 17%, rarely more than 50%; more in women than in men	Complete absence or very few intraparenchymal fat cells
Intracytoplasmic lipid	Abundant	Absent or scanty

Modified from Chan JKC: The parathyroid gland. In Fletcher CDM: Diagnostic histopathology of tumors, ed 4, Philadelphia, 2013, Elsevier Saunders, p 1274.

- Each gland measures approximately 3 to 6 mm in length.
- The combined weight increases from early infancy (mean, 5 to 9 mg) to the third or fourth decade (mean for males, 120 mg; for females, 142 mg).
- The actual parenchymal cell mass represents about 74% of the weight of adult parathyroid glands.
- Second rule, which is mutually inclusive of the first rule, is to recognize the resected tissue as parathyroid parenchyma:
 - Once recognized as parathyroid tissue, the determination of whether the resected tissue is normal, abnormal, or indeterminate can be undertaken (see [Table 34-1](#)).

INDICATIONS FOR INTRAOPERATIVE CONSULTATION FOR HYPERPARATHYROIDISM

- The purpose of intraoperative consultation of patients with hyperparathyroidism is to determine the underlying pathologic process, which directly affects treatment.
- A diagnosis of parathyroid adenoma results in excision of the involved gland alone, and this treatment is curative.
- A diagnosis of parathyroid hyperplasia results in subtotal parathyroidectomy (three and a half glands), leaving behind a small amount of parathyroid tissue (approximately 50 g).
- A diagnosis of parathyroid carcinoma usually necessitates en bloc resection to include the involved gland and adjacent thyroid lobe with or without selective neck dissection; this approach offers the best opportunity for a cure.

SURGEONS' EXPECTATIONS OF THE INTRAOPERATIVE ASSESSMENT OF PARATHYROID EXPLORATION

- Surgeons' expectations include:
 - Identify the tissue as being of parathyroid gland origin.
 - Attempt to differentiate a parathyroid adenoma from hyperplasia.
 - Identify carcinoma.
 - Do this all in a short time period.

PRACTICAL REALITY OF THE INTRAOPERATIVE ASSESSMENT OF PARATHYROID EXPLORATION

- First rule in the intraoperative consultation of parathyroid diseases is “do not believe the surgeon that the resected tissue is of parathyroid gland origin.”

HANDLING OF RESECTED PARATHYROID GLANDS

- Record location of excised tissue.
- Record the size and weight of the excised glands after removing the surrounding fat (inform surgeon of these findings):
 - Glands weighing greater than 60 mg are considered pathologic, whereas a normal gland typically weighs 35 mg.
 - Do not remove fat that is closely apposed to any nodules because this tissue may be representative of a cap of normal parathyroid tissue, a potential key histologic feature in the diagnosis of parathyroid adenoma.
- Gross examination with attention to the external appearance, color, and consistency of the excised gland
- Perform frozen section.

INKING OF PARATHYROID GLANDS

- Is the inking of parathyroid glands necessary?
 - Typically excised parathyroid glands do not require surgical ink, but if the excised gland is adherent to surrounding structures, suggesting the possible diagnosis of carcinoma, then evaluation of surgical margins becomes important and requires the inking of the tissue.

MICROSCOPIC FINDINGS AT FROZEN SECTION

([Figs. 34-1 through 34-8](#))

- In the presence of an enlarged (size and weight) parathyroid gland, the histologic findings are almost invariably abnormal.
- These changes may include increased cellularity and decreased stromal fat.
- A capsule may or may not be present, and a rim of residual normal or atrophic parathyroid tissue may or may not be present:
 - In this setting if the surgeon indicates that the remaining parathyroid glands are normal and/or

Fig. 34-1. Frozen section of normal adult parathyroid gland.

A, Low magnification shows an admixture of parenchymal (chief) cells and fat. **B**, The parenchymal (chief) cells are arranged in solid groups, cords, and nests with a single follicle-like structure containing eosinophilic material resembling colloid. **C**, Higher magnification shows a predominance of chief cells with round, hyperchromatic nuclei and amphophilic or slightly eosinophilic to somewhat clear cytoplasm, interspersed, scattered oxyphilic cells characterized by an eosinophilic granular cytoplasm, a follicle-like structure containing eosinophilic material resembling colloid, and associated fat cells (adipocytes).

Fig. 34-2. Intraoperative findings, parathyroid adenoma.

A, The parathyroid proliferative disease cellular proliferation (*middle and left*) is devoid of stromal fat, is encapsulated (*right of center*) separated from a "rim" of residual normal (non-proliferative) parathyroid gland with parenchymal fat (*lower right*). **B**, At slightly higher magnification, a thin fibrous capsule (*center*) separates the cellular proliferation (*left*) and residual normal parathyroid gland including adipocytes (*right*). **C**, At higher magnification, the fibrous capsule separates the adenoma (*left*) lacking intraparenchymal fat from the residual parathyroid parenchyma (*right*) with associated adipose cells. Note the nuclei of the adenoma are larger with a higher nuclear-to-cytoplasmic ratio as compared to the smaller nuclei with lower nuclear-to-cytoplasmic ratio of normal (residual) parathyroid gland.

Fig. 34-3. Intraoperative findings, parathyroid adenoma.

A, In this example, the cellular proliferative parathyroid lesion lacking associated intraparenchymal fat is surrounded by a fibrous capsule (*top*) but residual (normal or atrophic) parathyroid gland parenchyma was not identified. **B**, The parathyroid proliferative process shows a microfollicular pattern composed of chief cells and oncocytic cells; some of the microfollicular structures contain colloid-like material; stromal fat is absent. **C**, Higher magnification shows the relatively uniform nuclei of and admixture of chief cells and oncocytic cells. Clinically, this was the only enlarged gland, biopsy and frozen section of another gland was normal, and the rapid intraoperative parathyroid hormone level decreased to normal following removal of the enlarged gland. All of these features assisted in confirming the histologic consideration of a parathyroid adenoma.

samples of additional parathyroid glands show no abnormalities, then a diagnosis of “enlarged parathyroid gland consistent with adenoma” can be made.

- If more than one parathyroid gland is enlarged, including microscopic evidence of increased cellularity with decreased fat, the patient may have parathyroid hyperplasia:
 - Clinical information of whether the patient has a primary diagnosis of PPD, secondary hyperparathyroidism, or familial disease is helpful in the diagnosis.
 - Such examples can be signed out as “cellular parathyroid tissue” or “parathyroid proliferative disease,” with the definitive diagnosis pending permanent sections with appropriate clinical correlation.

MICROHYPERPLASIA

- In grossly normal (size and weight) glands classified into two groups:
 - Class II: hypercellularity only, not thought to produce hypercalcemia
 - Class III: nodular hyperplasia, abnormal cytology, or oxyphilic nodules are considered clinically significant
- The differentiation of an adenoma from hyperplasia in a single enlarged gland cannot always be determined by histopathologic evaluation:
 - Detailed clinical information (pre- and postoperative) is required to render this diagnosis.
 - In the face of abnormal parathyroid tissue in a single gland reported as “abnormal parathyroid gland [parathyroid proliferative disease]

Fig. 34-4. Intraoperative findings, parathyroid adenoma.

A, In this parathyroid proliferative disease process, acellular hyalinized fibrous bands course through the lesion, separating the proliferation into separate nodules. This feature is one often present in association with parathyroid carcinoma but may be seen in parathyroid adenomas too. **B**, Another example of a parathyroid adenoma with associated fibrosis and the appearance along the periphery of the lesion suggests the possible presence of infiltrative growth; in the middle to upper right of the image there is associated hemosiderin deposition. These are reactive and degenerative changes that resulted from a prior surgical procedure in the neck. These changes caused adherence to surrounding tissues, making the gland difficult to surgically excise, raising clinical concerns for a diagnosis of parathyroid carcinoma. However, the overall clinical and pathologic findings were those of a benign process, and long-term follow-up of the patient confirmed the diagnosis of a parathyroid adenoma.

Fig. 34-5. Intraoperative findings, parathyroid hyperplasia.

A, This enlarged parathyroid gland shows a diffuse cellular proliferation with absent intraparenchymal fat and no identifiable residual normal/atrophic parathyroid gland. **B**, The cellular proliferation is arranged in solid sheets, microfollicles, and gland-like structures. **C**, At higher magnification an admixture of chief cells and oncocyctic cells can be seen.

Fig. 34-6. Intraoperative findings, parathyroid hyperplasia.

A, This enlarged parathyroid gland shows nodular hyperplasia, absence of intraparenchymal fat, and no identifiable residual normal/atrophic parathyroid gland.

B, At higher magnification the nodules are composed entirely of chief cells or oncocytic cells.

consistent with adenoma or hyperplasia,” the pathologist should ask the surgeon about the status of the other parathyroid glands and should also request a biopsy (i.e., incisional biopsy) from one or more of the other parathyroid glands.

- In the presence of a borderline enlarged parathyroid gland with the other glands reported as normal, the considerations include:
 - An adenoma is present that has not been identified and continued surgical exploration is indicated.
 - The borderline enlarged gland is responsible for the hyperparathyroidism but this requires clinical correlation.
 - The elevated biochemical findings may be due to nonparathyroid hypercalcemic diseases.

FLOW CHART FOR INTRAOPERATIVE ASSESSMENT FOR HYPERPARATHYROIDISM

- Parathyroid confirmed → determine hypercellularity → enlarged, hypercellular gland confirmed → report as parathyroid proliferative disease c/w adenoma or hyperplasia → examine at least one additional parathyroid gland:
 - If other gland is normal or atrophic → c/w parathyroid adenoma
 - If other gland is abnormal (hypercellular) → c/w hyperplasia
- Parathyroid not confirmed → repeat biopsy

PITFALLS AND/OR ISSUES IN THE INTRAOPERATIVE EVALUATION OF PARATHYROID GLANDS

- Parathyroid tissue may be difficult to distinguish grossly from other tissues in the neck, including thyroid, lymph nodes, fat, and ectopic thymus; frozen section may be requested on these tissues:
 - The differentiation of parathyroid tissue from thyroid tissue may be problematic and is the most common reason for a deferred or incorrect frozen section diagnosis.
 - Histologic patterns that may result in misinterpretation include:
 - Follicle formation: in the presence of a micro-follicular pattern, features that may point to parathyroid gland rather than thyroid tissue include:
 - The presence of solid, sheet-like growth in the nodule
 - Variety of cell types (e.g., chief cells, clear cells, oncocytic cells)
 - The absence of a lymphocytic cell infiltrate
 - Fat cells within the nodule
 - A cap of normal, fat-containing parathyroid tissue adjacent to the nodule
- Lymph nodes can be mistaken for parathyroid tissue as a result of freezing artifact with the presence of tissue clefts and formation of ice crystals, giving the impression of stromal fat.
- Presence of a rim of adjacent parathyroid tissue is helpful in the diagnosis of parathyroid adenoma; however, this finding is not unequivocally diagnostic of a parathyroid adenoma:
 - A rim of adjacent parathyroid tissue is seen in 30% to 50% of cases at the time of frozen section,

Fig. 34-7. Intraoperative findings, parathyroid carcinoma.

A, Cellular parathyroid proliferative disease process showing acellular fibrous bands coursing through the proliferation and dividing it into multiple nodules. **B**, Trabecular growth. **C**, Solid growth and **(D)** acinar-type growth. **C** and **D**, The cells are rather monotonous appearing with limited nuclear pleomorphism and no increase in nuclear-to-cytoplasmic ratio, no macronucleoli and no increase in mitotic activity. Infiltrative growth including **(E)** into skeletal muscle and **(F)** adherence to and invasion of (not shown in this image) the thyroid gland (left) allow for intraoperative diagnosis of parathyroid carcinoma. Clinically, this patient had very high serum calcium and parathyroid hormone levels, and due to invasion the surgeon had difficulty resecting the gland.

Fig. 34-8. Intraoperative fat stain (Sudan IV).

A, Parenchymal cells in normal glands contain abundant cytoplasmic lipid droplets. **B**, Decrease intracellular/parenchymal lipid content in this hyperfunctioning chief cell proliferation.

and the pathologist cannot rely on this criterion alone to diagnose parathyroid adenoma.

- Further, a rim of normal parathyroid tissue may be seen in association with parathyroid hyperplasia.
- The most reliable distinction between parathyroid adenoma and parathyroid hyperplasia is made by thorough histologic evaluation of one or more additional parathyroid glands.
- Parathyroid hyperplasia may be dyssynchronous, so a hyperplastic gland may be only minimally enlarged.
- The greatest source of error in the intraoperative diagnosis of PPD is the overdiagnosis of parathyroid hyperplasia; however, this issue is currently less likely to be problematic because pathologists have become more aware of this diagnostic pitfall and there is a tendency for surgeons to favor resection of only grossly enlarged glands:

- As such, the false-positive diagnosis of hyperplasia is close to zero.
- Pathologists can minimize the overall error rate by being aware of the diagnostic pitfalls surrounding the intraoperative evaluation of parathyroid glands and by working in close communication with surgical colleagues.
- Presence of stromal fat cannot be used to exclude the diagnosis of adenoma as adenomas may contain variable amounts (some to abundant) of stromal fat.
- Issue of double (multiple) parathyroid adenomas is controversial:
 - Multiple adenomas have been reported with as high an incidence as 9.4%.
 - 9.4% reported incidence is challenged by reports in which multiple adenomas were not present in a large cohort of cases of consecutive explorations for primary hyperparathyroidism.
 - Surgeons who accept the existence of double adenomas advocate for routine bilateral neck exploration as the enlarged glands are approximately equally distributed on both sides of the neck.
- False-positive and false-negative diagnoses can occur in the interpretation of parathyroid carcinoma.

REEXPLORATION FOR PERSISTENT OR RECURRENT HYPERPARATHYROIDISM

- Persistent disease is defined as hyperparathyroidism that occurs within 6 months of prior surgery.
- Recurrent disease is defined as hyperparathyroidism that occurs more than 6 months after prior surgery.
- Due to alterations of the surgical anatomy, the identification of parathyroid glands during reexploration may prove difficult and the abnormal gland may be ectopically situated:
 - Scarring in the area may result in adhesions, creating surgical difficulty in removal of the parathyroid glands.
 - This clinical information may suggest a parathyroid carcinoma (see next section).

PARATHYROID CARCINOMA

- Parathyroid carcinoma typically presents as a mass that is adherent to adjacent structures; the latter would be indicative of invasion and invasion would be diagnostic for carcinoma.
- In cases of suspected parathyroid carcinoma, sampling the peripheral aspects of the lesion may provide the greatest yield in identifying invasion.

- In the face of a parathyroid carcinoma, the mass is excised en bloc and the evaluation of surgical margins is critical to determining that the tumor has been completely excised; however, in the absence of invasion, the light microscopic features may be suggestive of parathyroid carcinoma, but the frozen section diagnosis of parathyroid carcinoma can be extremely challenging.
- Pitfalls in the diagnosis of parathyroid carcinoma may include:
 - Prior violation of the neck by previous surgery or fine-needle aspiration biopsy or spontaneous infarction may result in adherence of the gland to adjacent structures, fibrous bands coursing within the gland, and/or necrosis.
 - In contrast to carcinoma, the adhesions in benign disease are usually easily dissected, there is evidence of hemorrhage (and other degenerative changes) within the fibrous bands, and the necrosis due to trauma or spontaneous infarction is usually large and confluent.
 - Mitotic figures can be seen in benign parathyroid lesions; the presence of mitoses is not in and of itself indicative of carcinoma.

PARATHYROID PROLIFERATIVE DISEASE (PPD) IN "ECTOPIC" SITES

- PPD may occur within the thyroid gland or thymus.
- These lesions are uncommon and typically benign (i.e., adenoma).
- Differentiating parathyroid from thyroid may be problematic (see above) and may require immunohistochemical stains (e.g., chromogranin, PTH, parafibromin, thyroglobulin and TTF1).
- Rare examples of intrathyroid parathyroid carcinoma have been reported.

ADJUNCT METHODS IN THE INTRAOPERATIVE EVALUATION OF PARATHYROID PROLIFERATIVE DISEASE

Fat Stains

- The use of intraoperative fat stains for the evaluation of parathyroid tissue is based on the fact that parenchymal cells in normal glands contain abundant cytoplasmic lipid droplets, whereas the intracellular or parenchymal lipid content is decreased or absent in hyperfunctioning chief cells.

- Fat stains may include Sudan IV, oil red O, and osmium carmine.
- Intraoperative fat stains are technically difficult and therefore not widely used.
- Cytoplasmic lipid droplets can be evaluated in air-dried cytologic preparations with Wright-Giemsa stain; in this setting lipid droplets are visible as clear vacuoles.

Density Gradients

- Mannitol density test or measurement provides an objective evaluation of the ratio of parenchymal-to-fat cells and is based on the differences in density between parenchymal cells and stromal fat cells.
- The density of the parathyroid is an indirect estimate of the lipid content of the parenchymal cell content.
- With knowledge of the glandular weight and estimate of parenchymal content, it is possible to calculate the parenchymal weight.
- This test is not widely used.

INTRAOPERATIVE MONITORING OF PARATHYROID HORMONE LEVELS

- Rapid intraoperative parathormone (IOPTH) evaluation levels by highly sensitive immunoradiometric assay (IRMA) are used for immediate biochemical confirmation of the result of parathyroid surgery.
- The parathyroid lesion is localized preoperatively and removed through a small incision.
- Because of the short half-life of PTH, a serum PTH level can be drawn 15 minutes after excision of the presumed diseased gland.
- Absence of a second or multiple lesions is confirmed by immediately checking blood parathyroid hormone level via the analyzer rather than by the standard method of exploration and biopsy of all the remaining parathyroid glands:
 - Adjunctive IOPTH monitoring facilitates a high cure rate for initial surgery of sporadic primary hyperparathyroidism.
 - Final IOPTH level that within the normal range dropping by more than 50% from baseline is a strong predictor of operative success.
 - Patients with a final IOPTH level between 41 and 65 pg/ml should be followed beyond 6 months for long-term recurrence.
- Rapid intraoperative parathormone evaluation allows for less invasive surgery and decreased operating time.

ACCURACY OF INTRAOPERATIVE CONFIRMATION OF PARATHYROID TISSUE AND INTRAOPERATIVE DIAGNOSIS

- Frozen section is a highly reliable means of identifying tissue type during parathyroid exploration.
- The frozen section accuracy rate of distinguishing parathyroid tissue from nonparathyroid tissue is reported to be 99.2%.

- A deferral rate of 0.4% due to difficulties in distinguishing between parathyroid gland and thyroid gland or lymph node
- Factors that may contribute to confounding the frozen section diagnosis include (separately or in combination): frozen section artifact, sampling error, and judgmental errors.

Multiple Endocrine Neoplasia (MEN) Syndromes

INTRODUCTION

See Chapter 28 under Medullary Thyroid Carcinoma for additional discussion.

- Multiple endocrine neoplastic (MEN) syndromes represent primarily autosomal dominant inherited disorders characterized by hyperplastic or neoplastic proliferations of more than one endocrine gland and include:
 - MEN type 1
 - MEN type 2 further divided into:
 - MEN-2A
 - MEN-2B
 - Familial medullary carcinoma (FMTc)

MEN TYPE 1

Synonym: Wermer syndrome

- Autosomal dominant disease:
 - May occur sporadically:
 - De novo mutations appear in 10% of all patients with MEN-1.
- Characterized by combined occurrence of two or more tumors involving:
 - Parathyroid glands
 - Pancreas
 - Anterior pituitary gland
- MEN-1 gene (MEN-1) is located on chromosome 11q13:
 - Composed of 10 exons that encode a 610 amino acid protein called menin
 - Menin interacts with several different proteins and plays an important role in regulation of cell growth, cell cycle, genome stability, and synapse plasticity.
- Tumors caused by a heterozygous germline-inactivating mutation in the MEN-1 gene (first hit) followed by somatic inactivating mutation or loss of the normal copy of the gene (second hit) leading to complete loss of function of encoded protein menin
- Familial MEN-1 has high degree of penetrance with clinical or biochemical manifestations of disease in 80% and 98%, respectively, by the fifth decade.
- Clinical manifestations related to tumor localizations and their secretory products:
 - Parathyroid glands:
 - Most common, occurring in 95% of MEN-1 patients
 - Chief cell hyperplasia
 - Clinically results in primary hyperparathyroidism
 - Pancreatic tumors
 - Occur in 40% to 70% of MEN-1 patients:
 - Tumors include:
 - Gastrinoma (G-cell tumors)
 - Most common pancreaticoduodenal tumor in MEN-1 (50%): approximately 20% of gastrinomas occur in MEN-1 patients; 20% to 60% of MEN-1 patients develop gastrinomas
 - Not always located in pancreas: significant proportion primarily arise in duodenum; other primary sites may include stomach, jejunum, bile ducts
 - Results in Zollinger-Ellison syndrome: clinical signs and symptoms related to gastric acid hypersecretion including: peptic ulcer disease; diarrhea; esophageal reflux disease
 - Insulinoma (beta cell tumors):
 - Occur in approximately 30% of MEN-1 patients
 - Clinical signs and symptoms related to insulin hypersecretion include hypoglycemic symptoms (hyperinsulinemic hypoglycemia); visual disturbances (blurred vision, diplopia); mental status changes including confusion, amnesia, behavioral changes.
 - Secondary effects of catecholamine release include hunger, weakness, nausea, palpitations, anxiety, perspiration.
 - Symptoms of Whipple triad include: hypoglycemia, low blood glucose levels, symptomatic relief with glucose administration.
 - Vasoactive intestinal peptide (VIP) cell tumors (VIPoma):
 - Occur in approximately 12% of MEN-1 patients

- Clinical signs and symptoms related to VIP hypersecretion include watery diarrhea associated with hypokalemia and achlorhydria (Verner-Morrison syndrome; pancreatic cholera; WDHA).
- Glucagonoma (alpha cell tumors):
 - Occur in less than 5% of MEN-1 patients
 - Clinical signs and symptoms related to glucagon hypersecretion include dermatitis (necrolytic migratory erythema), which is most common and usually found intertriginous and periorificial, especially groin and buttocks; diabetes mellitus and glucose intolerance; weight loss; anemia; hypohaminoacidemia.
- Pituitary tumors
 - Occur in 30% to 40% of MEN-1 patients
 - Anterior pituitary adenoma
 - Clinically results in acromegaly or hypopituitarism
- Other tumors described, including:
 - Adrenal cortical tumors
 - Carcinoid tumors (foregut, primarily thymus, and lung)
 - Nonendocrine tumors, including:
 - Lipomas, angiofibromas, collagenomas, and meningiomas
- Correlation between genotype and phenotype not found:
 - Combinations of tumors may be different in members of same family.
- Treatment for each type of endocrine tumor:
 - Generally similar as in non-MEN-1-associated tumors
 - Results are less successful owing to:
 - Multiplicity of tumors
 - Higher metastatic disease
 - Larger and more aggressive tumors
 - More resistant to treatment
- Untreated patients:
 - Have decreased life expectancy with 50% probability of death by the age of 50 years
 - Cause of death mostly directly related to MEN-1 is malignant pancreatic neuroendocrine tumors (NET) and thymic carcinoids
- Prognosis might improve by preclinical tumor diagnosis and appropriate treatment.

MEN TYPE 2

- Autosomal dominant disease caused by germline mutation of *RET* (REarranged during Transfection) gene
- Characterized by various endocrine tumors of:
 - Thyroid gland
 - Adrenal gland

- Parathyroid glands
- As well as abnormalities of nonendocrine organs
- Three clinical subtypes:
 - MEN-2A
 - MEN-2B
 - Familial medullary thyroid carcinoma (FMTC)
- Hallmark of MEN-2 is very high lifetime risk of developing medullary thyroid carcinoma (MTC):
 - >95% in untreated patients
 - Collectively associated with a 70% to 100% risk of MTC by age 70 years
- Recent report that germline mutations in *CDKN1B* can predispose to development of multiple endocrine tumors in rats and humans:
 - New MEN syndrome named MEN-X and MEN-4, respectively

MEN-2A

Synonym: Sipple syndrome

- Most common of three subtypes, accounting for 75% to 90% of familial cases
- Germline point mutation of *RET* protooncogene
 - Usually involve exon 10 and 11
 - Most common genetic abnormality found in 95% of families with MEN-2A
- Characterized by presence of:
 - Thyroid lesions/tumors often multiple and bilateral, including:
 - Medullary thyroid carcinoma (MTC)
 - Usual first manifestation of syndrome
 - C-cell hyperplasia:
 - May precede clinically obvious MTC
 - Pheochromocytoma (approximately 50%):
 - Often bilateral
 - Accompanied by adrenal medullary hyperplasia
 - Primary parathyroid (chief cell) hyperplasia (20% to 30%)
 - Rare cases associated with Hirschsprung disease and cutaneous lichen amyloidosis
- Genetic testing for *RET* protooncogene has largely replaced serum calcitonin measurement (following gastrin administration) for diagnosis.

MEN-2B

Synonyms: Gorlin syndrome; Wagenmann-Froboese syndrome

- Least common of 3 subtypes, accounting for approximately 5% of familial cases
- Germline mutation of *RET* protooncogene:
 - Point mutation at exon 16:
 - Replacement of methionine by threonine at codon 918
 - Identified in 95% of cases with MEN-2B

- Characterized by presence of:
 - Medullary thyroid carcinoma
 - Pheochromocytoma (approximately 50%)
 - Mucosal neuroma (oral mucosa, lips, tongue, eyelids):
 - Most constant feature
 - Gastrointestinal ganglioneuromatosis (100%)
 - May represent initial manifestation of disease
 - May present with clinical picture identical to Hirschsprung disease
 - Rectal biopsy reveals proliferation rather than absence of ganglia
 - Marfanoid appearance (100%)
 - Rarely associated with parathyroid hyperplasia
 - Genetic testing for RET protooncogene has largely replaced serum calcitonin measurement for diagnosis of hereditary MTC.

Familial MTC (FMTC)

Synonym: MTC alone

- Second most common of three subtypes, accounting for approximately 15% of familial cases
- Not associated with lesions of other organs (hence designation as MTC alone)
- Germline mutation of RET protooncogene
 - 85% of families will show mutations in codons of exons 10 and 11
 - Mutations in codons 768, 790, 791, 804, 848, 883, 891, 904
- Genetic testing for RET protooncogene has largely replaced serum calcitonin measurement for diagnosis of hereditary MTC.

Treatment and Prognosis

- Early detection and curative surgery can result in cure in virtually all children after appropriate genetic testing at a young age.
 - Genetic testing should be performed before surgical intervention in all patients diagnosed with MTC.
- In MTCs seen clinically because genetic testing was not performed or because patient represents index case in a family, prognosis mirrors that of sporadic tumors (see Chapter 28) except for high frequency of multiple primary tumors.
- Effective management of patients with MEN-2A, MEN-2B, and FMTC depends on understanding of variable behavior of disease expression in patients with a specific RET mutation.
- Strong genotype-phenotype correlations exist with respect to clinical subtype, age at onset, and aggressiveness of MTC.
 - Used to determine age at which prophylactic thyroidectomy should occur and whether screening

for pheochromocytoma or hyperparathyroidism is necessary

- Specific RET mutations can impact management in patients presenting with apparently sporadic MTC.
- Relative aggressiveness of MTC associated with specific RET mutations, including:
 - Presence of codon 918 mutation:
 - Indicative of aggressive disease phenotype whether mutation is hereditary (MEN-2B) or acquired as somatic mutation
 - Surgery performed in first month of life or as soon as phenotype identified
 - Presence of codon 634 RET mutation:
 - Aggressive phenotype accounting for approximately 80% of hereditary MTC
 - Surgery performed <5 years of age
 - Presence of mutations of codons 768, 790, 791, and 804:
 - In certain kindreds these mutations associated with metastasis and death
 - In other kindreds these mutations never associated with death
 - Consideration for surgery <5 years of age or delay in following criteria met:
 - Less aggressive family history
 - Normal serum calcitonin
 - Normal neck ultrasound
- RET analysis in MEN has revolutionized management of MEN-2 and allowed surgical prediction and prophylaxis to take place.
- Prognosis related to pheochromocytoma and parathyroid tumors similar to that of sporadic counterparts

INHERITED SYNDROMES WITH DIFFERENT ENDOCRINE NEOPLASMS

- Heterogeneous group of cancer susceptibility syndromes that affect one or more of endocrine glands or neuroendocrine tissues that include:
 - Hyperparathyroid-jaw tumor syndrome: (see Sections 2 and 9)
 - Endocrine tumor:
 - Parathyroid adenoma or carcinoma
 - Fibroosseous lesions of mandible or maxilla
 - Renal cysts and tumors
 - von Hippel-Lindau disease (see Section 7)
 - Endocrine tumors:
 - Pheochromocytoma, pancreatic endocrine tumors
 - Hemangioblastoma
 - Renal cell carcinoma

- Endolymphatic sac papillary tumor
- Others
- Carney complex (see Section 7)
 - Endocrine tumor:
 - Pituitary adenoma
 - Primary pigmented nodular adrenocortical disease
 - Cardiac myxoma
 - Psammomatous melanotic schwannoma
- Neurofibromatosis type 1 (see Section 4)
 - Endocrine tumor:
 - Pheochromocytoma
 - Paraganglioma (rare)
 - Neurofibromas
 - Café-au-lait skin pigmentation
 - Axillary freckling or freckling in inguinal region
 - Iris hamartomas (Lisch nodules)
 - Central nervous system gliomas
- Cowden syndrome (see Section 8)
 - Endocrine tumor/lesion:
 - Follicular neoplasms (adenoma and carcinoma)
 - Adenomatoid nodules (goiter)
 - Macrocephaly
 - Intestinal hamartomatous polyps
 - Benign skin tumors (trichilemmoma, papillomatous papules, acral keratoses)
- Familial paraganglioma-pheochromocytoma syndromes (see Section 4)
- McCune-Albright syndrome (see Section 2)
 - Endocrine lesions:
 - Autonomous endocrine hyperfunction (e.g., gonadotropin-independent precocious puberty)
 - Other endocrine syndromes may include hyperthyroidism, acromegaly, and Cushing syndrome.
 - Polyostotic fibrous dysplasia
 - Café-au-lait skin pigmentation
